CONTENTS

Foreword	xv
Preface	xvii
Contributors	xix
1. Fundamentals of Acoustics, Noise, and Vibration <i>Malcolm J. Crocker</i>	1
PART I. Fundamentals of Acoustics and Noise	17
2. Theory of Sound—Predictions and Measurement <i>Malcolm J. Crocker</i>	19
3. Sound Sources <i>Philip A. Nelson</i>	43
4. Sound Propagation in Rooms <i>K. Heinrich Kuttruff</i>	52
5. Sound Propagation in the Atmosphere <i>Keith Attenborough</i>	67
6. Sound Radiation from Structures and Their Response to Sound <i>Jean-Louis Guyader</i>	79
7. Numerical Acoustical Modeling (Finite Element Modeling) <i>R. Jeremy Astley</i>	101
8. Boundary Element Modeling <i>D. W. Herrin, T. W. Wu, and A. F. Seybert</i>	116
9. Aerodynamic Noise: Theory and Applications <i>Philip J. Morris and Geoffrey M. Lilley</i>	128
10. Nonlinear Acoustics <i>Oleg V. Rudenko and Malcolm J. Crocker</i>	159
PART II. Fundamentals of Vibration	169
11. General Introduction to Vibration <i>Bjorn A. T. Petersson</i>	171
12. Vibration of Simple Discrete and Continuous Systems <i>Yuri I. Bobrovnikskii</i>	180
13. Random Vibration <i>David E. Newland</i>	205
14. Response of Systems to Shock <i>Charles Robert Welch and Robert M. Ebeling</i>	212

15. Passive Damping <i>Daniel J. Inman</i>	225
16. Structure-Borne Energy Flow <i>Goran Pavić</i>	232
17. Statistical Energy Analysis <i>Jerome E. Manning</i>	241
18. Nonlinear Vibration <i>Lawrence N. Virgin, Earl H. Dowell, and George Flowers</i>	255
PART III. Human Hearing and Speech	269
19. General Introduction to Human Hearing and Speech <i>Karl T. Kalveram</i>	271
20. The Ear: Its Structure and Function, Related to Hearing <i>Hiroshi Wada</i>	277
21. Hearing Thresholds, Loudness of Sound, and Sound Adaptation <i>William A. Yost,</i>	286
22. Speech Production and Speech Intelligibility <i>Christine H. Shadle</i>	293
PART IV. Effects of Noise, Blast, Vibration, and Shock on People	301
23. General Introduction to Noise and Vibration Effects on People and Hearing Conservation <i>Malcolm J. Crocker</i>	303
24. Sleep Disturbance due to Transportation Noise Exposure <i>Lawrence S. Finegold, Alain G. Muzet, and Bernard F. Berry</i>	308
25. Noise-Induced Annoyance <i>Sandford Fidell</i>	316
26. Effects of Infrasound, Low-Frequency Noise, and Ultrasound on People <i>Norm Broner</i>	320
27. Auditory Hazards of Impulse and Impact Noise <i>Donald Henderson and Roger P. Hamernik</i>	326
28. Effects of Intense Noise on People and Hearing Loss <i>Rickie R. Davis and William J. Murphy</i>	337
29. Effects of Vibration on People <i>Michael J. Griffin</i>	343
30. Effects of Mechanical Shock on People <i>A. J. Brammer</i>	354
31. Hearing Protectors <i>Samir N. Y. Gerges and John G. Casali</i>	364
32. Development of Standards and Regulations for Occupational Noise <i>Alice H. Suter</i>	377
33. Hearing Conservation Programs <i>John Erdreich</i>	383
34. Rating Measures, Descriptors, Criteria, and Procedures for Determining Human Response to Noise <i>Malcolm J. Crocker</i>	394

PART V. Noise and Vibration Transducers, Analysis Equipment, Signal Processing, and Measuring Techniques	415
35. General Introduction to Noise and Vibration Transducers, Measuring Equipment, Measurements, Signal Acquisition, and Processing <i>Malcolm J. Crocker</i>	417
36. Acoustical Transducer Principles and Types of Microphones <i>Gunnar Rasmussen and Per Rasmussen</i>	435
37. Vibration Transducer Principles and Types of Vibration Transducers <i>Colin H. Hansen</i>	444
38. Sound Level Meters <i>George S. K. Wong</i>	455
39. Noise Dosimeters <i>Chucri A. Kardous</i>	465
40. Analyzers and Signal Generators <i>Henrik Herlufsen, Svend Gade, and Harry K. Zaveri</i>	470
41. Equipment for Data Acquisition <i>Zhuang Li and Malcolm J. Crocker</i>	486
42. Signal Processing <i>Allan G. Piersol</i>	493
43. Noise and Vibration Measurements <i>Pedro R. Valletta and Malcolm J. Crocker</i>	501
44. Determination of Sound Power Level and Emission Sound Pressure Level <i>Hans G. Jonasson</i>	526
45. Sound Intensity Measurements <i>Finn Jacobsen</i>	534
46. Noise and Vibration Data Analysis <i>Robert B. Randall</i>	549
47. Modal Analysis and Modal Testing <i>David J. Ewins</i>	565
48. Machinery Condition Monitoring <i>Robert B. Randall</i>	575
49. Wavelet Analysis of Vibration Signals <i>David E. Newland</i>	585
50. Use of Near-Field Acoustical Holography in Noise and Vibration Measurements <i>Earl G. Williams</i>	598
51. Calibration of Measurement Microphones <i>Erling Frederiksen</i>	612
52. Calibration of Shock and Vibration Transducers <i>Torben Rask Licht</i>	624
53. Metrology and Traceability of Vibration and Shock Measurements <i>Hans-Jürgen von Martens</i>	633
PART VI. Principles of Noise and Vibration Control and Quiet Machinery Design	647
54. Introduction to Principles of Noise and Vibration Control <i>Malcolm J. Crocker</i>	649

55. Noise and Vibration Source Identification <i>Malcolm J. Crocker</i>	668
56. Use of Enclosures <i>Jorge P. Arenas and Malcolm J. Crocker</i>	685
57. Use of Sound-Absorbing Materials <i>Malcolm J. Crocker and Jorge P. Arenas</i>	696
58. Use of Barriers <i>Jorge P. Arenas</i>	714
59. Use of Vibration Isolation <i>Eric E. Ungar</i>	725
60. Damping of Structures and Use of Damping Materials <i>Eric E. Ungar</i>	734
61. Dynamic Vibration Absorbers <i>Leif Kari</i>	745
62. Rotor Balancing and Unbalance-Caused Vibration <i>Maurice L. Adams, Jr.</i>	753
63. Active Noise Control <i>Stephen J. Elliott</i>	761
64. Active Vibration Control <i>Christopher Fuller</i>	770
65. Microelectromechanical Systems (MEMS) Sensors for Noise and Vibration Applications <i>James J. Allen</i>	785
66. Design of Low-Noise Machinery <i>Michael Bockhoff</i>	794
67. Psychoacoustics and Product Sound Quality <i>Malcolm J. Crocker</i>	805
PART VII. Industrial and Machine Element Noise and Vibration Sources—Prediction and Control	829
68. Machinery Noise and Vibration Sources <i>Malcolm J. Crocker</i>	831
69. Gear Noise and Vibration Prediction and Control Methods <i>Donald R. Houser</i>	847
70. Types of Bearings and Means of Noise and Vibration Prediction and Control <i>George Zusman</i>	857
71. Centrifugal and Axial Fan Noise Prediction and Control <i>Gerald C. Lauchle</i>	868
72. Types of Electric Motors and Noise and Vibration Prediction and Control Methods <i>George Zusman</i>	885
73. Pumps and Pumping System Noise and Vibration Prediction and Control <i>Mirko Čudina</i>	897

FOREWORD

When the term *noise control* became prevalent in the middle of the last century, I didn't like it very much. It seemed to me to regard all sound from products as undesirable, to be treated by the add-ons in the form of barriers, silencers, and isolators. Now I know that many practitioners of this art are more sophisticated than that, as a perusal of the material in this excellent book will show. Therefore, we have to be appreciative of the work by the editor and the assembly of expert authors he has brought together. They have shown that in order to make products quieter and even more pleasing to listen to, you have to attack the noise in the basic design process, and that requires understanding basic physics of sound generation and propagation. It also requires that we understand how people are affected by sounds in both undesirable and favorable ways.

The early chapters discuss fundamental ideas of sound, vibration, propagation, and human response. Most active practitioners in noise control will already have this background, but it is common for an engineer who has a background in, say, heat transfer to be asked to become knowledgeable in acoustics and work on product noise problems. Lack of background can be made up by attending one or more courses in acoustics and noise control, and this book can be a powerful addition in that process. Indeed, the first five major sections of the book provide adequate material for such an educational effort.

Most engineers will agree that if possible it is better to keep the noise from being generated in the first place rather than blocking or absorbing it after it has already been generated. The principles for designing quieter components such as motors, gears, and fans are presented in the next chapters. When noise is reduced by add-ons that increase product weight and size, or interfere with cooling and make material choices more difficult, the design and/or selection of quiet components becomes attractive. These chapters will help the design engineer to get started on the process.

The reliance on add-ons continues to be a large part of noise control activity, and that subject is covered here in chapters on barriers, sound absorbers, and vibration isolation and damping. The relatively new topic of active noise reduction is also here. These add-on treatments still have to be designed to provide the performance needed, and much of the time those responsible for reducing product sound do not have the ability to redesign a noisy component; so an add-on may be the only practical choice.

Transportation is a source of noise for the owner/user of vehicles and for bystanders as well. As users, most of us want quiet pleasing sounding interiors, and the technology for achieving that sound is widely employed. It is in this area in particular that ideas for sound quality—achieving the right sound for the product—have received the greatest emphasis.

The sound of a dishwasher in the kitchen directly impacts the owner/user of that product, but the owner/user also gets the benefit of the product. But in many cases, the effects of product noise are also borne by others who do not get the benefit. The sounds of aircraft, automobile traffic, trains, construction equipment, and industrial plants impact not only the beneficiaries of those devices but the bystanders as well. In these cases, national, state, and local governments have a role to play as honest brokers, trying to balance the costs and benefits of noise control alternatives. Should highway noise be mitigated by barriers or new types of road surfaces? Why do residents on one side of a street receive noise reduction treatments for aircraft noise at their house while those across the street do not, simply because a line

has to be drawn somewhere? And should aircraft noise be dealt with by insulating homes or by doing more research to make aircraft quieter? How is the balance to be struck between locomotive whistles that disturb neighbors and better crossing safety?

These policy issues are not easy, but to the credit of the editor and the authors, the book brings such issues to the fore in a final set of chapters. The editor and the authors are to be congratulated for tackling this project with professionalism and dedication, and bringing to all of us a terrific book on an important subject.

Richard H. Lyon

Belmont, Massachusetts

PREFACE

This book is designed to fill the need for a comprehensive resource on noise and vibration control. Several books and journals on noise control, and others on vibration control already exist. So why another book and why combine both topics in one book? First, most books cover only a limited number of topics in noise or vibration and in many cases their treatment has become dated. Second is the fact that noise and vibration have a close physical relationship. Vibrating systems make noise, and noise makes structural systems vibrate. There are several other reasons to include both topics in one book. People are adversely affected by both noise and vibration and, if sufficiently intense, both noise and vibration can permanently hurt people. Also, structural systems, if excited by excessive noise and vibration over sufficient periods of time, can fatigue and fail. There are other reasons as well. Because noise and vibration are both dynamic processes, similar measurement systems, signal processing methods and data analysis techniques can be used to study both phenomena. In the prediction of noise and vibration, similar analytical and numerical approaches such as the finite element and boundary element methods and the statistical energy analysis approach can also be used for both.

Considerable progress has been made in recent years in making quieter machinery, appliances, vehicles and aircraft. This is particularly true for mass produced items for which development costs can be spread over a large production run and where sufficient expenditures on noise and vibration reduction can be justified. Significant progress has also been made in the case of some very expensive first cost machines such as passenger aircraft, in which large sums have been spent successfully to make them quieter. In many such cases, most of the simple noise and vibration reduction measures have already been taken and further noise and vibration reduction involves much more sophisticated experimental and theoretical approaches such as those described in some of the chapters in this book. Some problems such as those involving community noise, and noise and vibration control of buildings, can be overcome with well known and less sophisticated approaches as described in other chapters, provided the techniques are properly applied.

This book was conceived to meet the needs of many different individuals with varying backgrounds as they confront a variety of noise and vibration problems. First a detailed outline for the handbook was prepared and an editorial board selected whose members provided valuable assistance in refining the outline and in making suggestions for the choice of authors. By the time the authors were selected, the complete handbook outline, including the detailed contents for each chapter, was well advanced. This was supplied to each author. This approach made it possible to minimize overlap of topics, and to ensure adequate cross referencing.

To prevent the handbook becoming too long, each author was given a page allowance. Some chapters such as those on compressors, fans, and mufflers were given a greater page allowance because so many are in use around the world. Each author was asked to write at a level accessible to general readers and not just to specialists and to provide suitable, up-to-date references for readers who may wish to study the subject in more depth. I believe that most authors have responded admirably to the challenge.

The handbook is divided into 11 main parts and contains a total of 130 chapters. Three additional parts contain the glossary, index and list of reviewers. Each of the 11 main parts starts with a general review

chapter which serves as an introduction to that part and also at the same time helps in cross-referencing the topics covered in that part of the book and other relevant chapters throughout the handbook. These introductory review chapters also sometimes cover additional topics not discussed elsewhere in the book. It was impossible to provide extended discussion of all topics relating to noise, shock, and vibration in this volume. Readers will find many topics treated in more detail in my *Encyclopedia of Acoustics* (1997) and *Handbook of Acoustics* (1998), both published by John Wiley and Sons, New York. The first chapter in the handbook provides an introduction to some of the fundamentals of acoustics, noise, and vibration for those who do not feel it necessary to study the more advanced acoustics and vibration treatments provided in Parts 1 and 2 of the book.

The division of the chapters into 11 main parts of the book is somewhat arbitrary, but at the same time logical. Coverage includes fundamentals of acoustics and noise; fundamentals of vibration; human hearing and speech; effects of noise, blast, vibration and shock on people; noise and vibration analysis equipment, signal processing and measurements; industrial and machine element noise and vibration sources; exterior and interior transportation vehicle noise and vibration sources; noise and vibration control of buildings, and community noise and vibration. The book concludes with a comprehensive glossary and index and a list of the chapter reviewers. The glossary was compiled by Zhuang Li and the editor, with substantial and valuable inputs also from all of the authors of the book. In addition, although the index was mostly my own work with valuable assistance provided by my staff, again authors provided important suggestions for the inclusion of key words.

I am very much indebted to more than 250 reviewers who donated their time to read the first drafts of all of the chapters including my own and who made very valuable comments and suggestions for improvement. Their anonymous comments were supplied to the authors, to help them as they finalized their chapters. Many of the reviewers were members of the International Institute of Acoustics and Vibration, who were able to supply comments and suggestions from a truly international perspective. The international character of this handbook becomes evident when one considers the fact that the authors are from 18 different countries and the reviewers from over 30 countries.

In view of the international character of this book, the authors were asked to use metric units and recognized international terminology wherever possible. This was not always possible where tables or figures are reproduced from other sources in which the American system of units is still used. The acoustics and vibration terminology recommended by the International Standardization Organisation (ISO) has also been used wherever possible. So, for example, terminology such as sound level, dB(A) is replaced by A-weighted sound pressure level, dB; and sound power level, dB(A) is replaced by A-weighted sound power level, dB. This terminology, although sometimes more cumbersome, is preferred in this book because it reduces potential confusion between sound pressure levels and sound power levels and does not mix up the A-weighting with the decibel unit. Again it has not always been possible to make these changes in the reproduction of tables and figures of others.

I would like to thank all the authors who contributed chapters to this book for their hard work. In many cases the editorial board provided considerable help. Henning von Gierke, in particular, was very insistent that vibration be given equal weight to noise and I followed his wise advice closely. I wish to thank my assistants, Angela Woods, Elizabeth Green and especially Renata Gallyamova, all of whom provided really splendid assistance in making this book possible. I am also indebted to my students, in particular Zhuang Li and Cédric Béchet, who helped proofread and check the final versions of my own chapters and many others throughout this book. The editorial staff at Wiley must also be thanked, especially Bob Hilbert, who guided this *Handbook* to a successful conclusion. Last and not least, I should like to thank my wife Ruth and daughters Anne and Elizabeth for their support, patience and understanding during the preparation of this book.

CHAPTER 1

FUNDAMENTALS OF ACOUSTICS, NOISE, AND VIBRATION

Malcolm J. Crocker
Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

The vibrations in machines and structures result in oscillatory motion that propagates in air and/or water and that is known as sound. Sound can also be produced by the oscillatory motion of the fluid itself, such as in the case of the turbulent mixing of a jet with the atmosphere, in which no vibrating structure is involved. The simplest type of oscillation in vibration and sound phenomena is known as simple harmonic motion, which can be shown to be sinusoidal in time. Simple harmonic motion is of academic interest because it is easy to treat and manipulate mathematically; but it is also of practical interest. Most musical instruments make tones that are approximately periodic and simple harmonic in nature. Some machines (such as electric motors, fans, gears, etc.) vibrate and make sounds that have pure tone components. Musical instruments and machines normally produce several pure tones simultaneously. Machines also produce sound that is not simple harmonic but is random in time and is known as noise. The simplest vibration to analyze is that of a mass–spring–damper system. This elementary system is a useful model for the study of many simple vibration problems. Sound waves are composed of the oscillatory motion of air (or water) molecules. In air and water, the fluid is compressible and the motion is accompanied by a change in pressure known as sound. The simplest form of sound is one-dimensional plane wave propagation. In many practical cases (such as in enclosed spaces or outdoors in the environment) sound propagation in three dimensions must be considered.

2 DISCUSSION

In Chapter 1 we will discuss some simple theory that is useful in the control of noise and vibration. For more extensive discussions on sound and vibration fundamentals, the reader is referred to more detailed treatments available in several books.^{1–7} We start off by discussing simple harmonic motion. This is because very often oscillatory motion, whether it be the vibration of a body or the propagation of a sound wave, is like this idealized case. Next, we introduce the ideas of period, frequency, phase, displacement, velocity, and acceleration. Then we study free and forced vibration of a simple mass–spring system and the influence of damping forces on the system. These vibration topics are discussed again at a more advanced level in Chapters 12, 15, and 60. In Section 5 we

discuss how sound propagates in waves, and then we study *sound intensity* and *energy density*. In Section 6 we consider the use of decibels to express *sound pressure levels*, *sound intensity levels*, and *sound power levels*. Section 7 describes some preliminary ideas about human hearing. In Sections 8 and 9, we study frequency analysis of sound and frequency weightings and finally in Section 10 day–night and day–evening–night sound pressure levels.

In Chapter 2 we discuss some further aspects of sound propagation at a more intermediate level, including the radiation of sound from idealized spherical sources, standing waves, and the important ideas of *near*, *far*, *free*, and *reverberant* sound fields. We also study the propagation of sound in closed spaces indoors and outdoors. This has applications to industrial noise control problems in buildings and to community noise problems, respectively. Chapter 2 also serves as an introduction to some of the topics that follow in Part I of this handbook.

3 SIMPLE HARMONIC MOTION

The motion of vibrating systems such as parts of machines, and the variation of sound pressure with time is often said to be simple harmonic. Let us examine what is meant by simple harmonic motion.

Suppose a point P is revolving around an origin O with a constant angular velocity ω , as shown in Fig. 1.

Figure 1 Representation of simple harmonic motion by projection of the rotating vector A on the X or Y axis.

Figure 2 Simple harmonic motion.

If the vector OP is aligned in the direction OX when time $t = 0$, then after t seconds the angle between OP and OX is ωt . Suppose OP has a length A , then the projection on the X axis is $A \cos \omega t$ and on the Y axis, $A \sin \omega t$. The variation of the projected length on either the X axis or the Y axis with time is said to represent simple harmonic motion.

It is easy to generate a displacement vs. time plot with this model, as is shown in Fig. 2. The projections on the X axis and Y axis are as before. If we move the circle to the right at a constant speed, then the point P traces out a curve $y = A \sin \omega t$, horizontally. If we move the circle vertically upwards at the same speed, then the point P would trace out a curve $x = A \cos \omega t$, vertically.

3.1 Period, Frequency, and Phase

The motion is seen to repeat itself every time the vector OP rotates once (in Fig. 1) or after time T seconds (in Figs. 2 and 3). When the motion has repeated itself, the displacement y is said to have gone through one *cycle*. The number of cycles that occur per second is called the *frequency* f . Frequency may be expressed in cycles per second or, equivalently in hertz, or as abbreviated, Hz. The use of hertz or Hz is preferable because this has become internationally agreed upon as the unit of frequency. (Note cycles per second = hertz). Thus

$$f = 1/T \text{ hertz} \quad (1)$$

The time T is known as the *period* and is usually measured in seconds. From Figs. 2 and 3, we see that the motion repeats itself every time ωt increases by 2π , since $\sin 0 = \sin 2\pi = \sin 4\pi = 0$, and so on. Thus $\omega T = 2\pi$ and from Eq. 1,

$$\omega = 2\pi f \quad (2)$$

The angular frequency, ω , is expressed in radians per second (rad/s).

The motion described by the displacement y in Fig. 2 or the projection OP on the X or Y axes in Fig. 2 is said to be *simple harmonic*. We must now discuss something called the *initial phase angle*, which is sometimes just called *phase*. For the case we have chosen in Fig. 2, the phase angle is zero. If, instead, we start counting time from when the vector points in the direction OP_1 , as shown in Fig. 3, and we let the angle $XOP_1 = \phi$, this is equivalent to moving the time origin t seconds to the right in Fig. 2. Time is started when P is at P_1 and thus the initial displacement is $A \sin \phi$. The *initial phase angle* is ϕ . After time t , P_1 has moved to P_2 and the displacement

$$y = A \sin(\omega t + \phi) \quad (3)$$

If the initial phase angle $\phi = 0^\circ$, then $y = A \sin \omega t$; if the phase angle $\phi = 90^\circ$, then $y = A \sin(\omega t + \pi/2) \equiv A \cos \omega t$. For mathematical convenience, complex exponential notation is often used. If the displacement is written as

$$y = A e^{j\omega t}, \quad (3a)$$

and we remember that $A e^{j\omega t} = A(\cos \omega t + j \sin \omega t)$, we see in Fig. 1 that the real part of Eq. (3a) is represented by the projection of the point P onto the x axis, $A \cos \omega t$, and of the point P onto the y or imaginary axis, $A \sin \omega t$. Simple harmonic motion, then, is often written as the real part of $A e^{j\omega t}$, or in the more general form $A e^{j(\omega t + \phi)}$. If the constant A is made complex, then the displacement can be written as the real part of $A e^{j\omega t}$, where $A = A e^{j\phi}$.

3.2 Velocity and Acceleration

So far we have examined the displacement y of a point. Note that, when the displacement is in the OY direction, we say it is positive; when it is in

Figure 3 Simple harmonic motion with initial phase angle ϕ .

the opposite direction to OY , we say it is negative. Displacement, velocity, and acceleration are really vector quantities in mathematics; that is, they have magnitude and direction. The velocity v of a point is the rate of change of position with time of the point x in metres/second. The acceleration a is the rate of change of velocity with time. Thus, using simple calculus:

$$v = \frac{dy}{dt} = \frac{d}{dt}[A \sin(\omega t + \phi)] = A\omega \cos(\omega t + \phi) \quad (4)$$

and

$$a = \frac{dv}{dt} = \frac{d}{dt}[A\omega \cos(\omega t + \phi)] = -A\omega^2 \sin(\omega t + \phi) \quad (5)$$

Equations (3), (4), and (5) are plotted in Fig. 4.

Note, by trigonometric manipulation we can rewrite Eqs. (4) and (5) as (6) and (7):

$$v = A\omega \cos(\omega t + \phi) = A\omega \sin\left(\omega t + \frac{\pi}{2} + \phi\right) \quad (6)$$

and

$$a = -A\omega^2 \sin(\omega t + \phi) = +A\omega^2 \sin(\omega t + \pi + \phi) \quad (7)$$

and from Eq. (3) we see that $a = -\omega^2 y$.

Equations (3), (6), and (7) tell us that for simple harmonic motion the *amplitude* of the velocity is ω or $2\pi f$ greater than the *amplitude* of the displacement, while the *amplitude* of the acceleration is ω^2 or $(2\pi f)^2$

Figure 4 Displacement, velocity, and acceleration.

greater. The *phase* of the velocity is $\pi/2$ or 90° ahead of the displacement, while the acceleration is π or 180° ahead of the displacement.

Note, we could have come to the same conclusions and much more quickly if we had used the complex exponential notation. Writing

$$y = Ae^{j\omega t}$$

then

$$v = Aj\omega e^{j\omega t} = j\omega y$$

and

$$a = A(j)^2 \omega^2 e^{j\omega t} = -A\omega^2 e^{j\omega t} = -\omega^2 y$$

4 VIBRATING SYSTEMS

4.1 Mass-Spring System

A. Free Vibration – Undamped Suppose a mass of M kilogram is placed on a spring of stiffness K newton-metre (see Fig. 5a), and the mass is allowed to sink down a distance d metres to its equilibrium position under its own weight Mg newtons, where g is the acceleration of gravity 9.81 m/s^2 . Taking forces and deflections to be positive upward gives

$$-Mg = -Kd \quad (8)$$

thus the static deflection d of the mass is

$$d = Mg/K \quad (8a)$$

The distance d is normally called the *static deflection* of the mass; we define a new displacement coordinate system, where $Y = 0$ is the location of the mass after the gravity force is allowed to compress the spring.

Suppose now we displace the mass a distance y from its equilibrium position and release it; then it will oscillate about this position. We will measure the deflection from the equilibrium position of the mass (see Fig. 5b). Newton's law states that force is equal to mass \times acceleration. Forces and deflections are again assumed positive upward, and thus

$$-Ky = M \frac{d^2 y}{dt^2} \quad (9)$$

Let us assume a solution to Eq. (9) of the form $y = A \sin(\omega t + \phi)$. Then upon substitution into Eq. (9) we obtain

$$-KA \sin(\omega t + \phi) = M[-\omega^2 \sin(\omega t + \phi)]$$

We see our solution satisfies Eq. (9) only if

$$\omega^2 = K/M$$

The system vibrates with free vibration at an angular frequency ω radians/second. This frequency, ω , which is generally known as the *natural* angular frequency, depends only on the stiffness K and

Figure 5 Movement of mass on a spring: (a) static deflection due to gravity and (b) oscillation due to initial displacement y_0 .

mass M . We normally signify this so-called natural frequency with the subscript n . And so

$$\omega_n = \sqrt{K/M}$$

and from Eq. (2)

$$f_n = \frac{1}{2\pi} \sqrt{K/M} \text{ Hz} \quad (10)$$

The frequency, f_n hertz, is known as the *natural frequency* of the mass on the spring. This result, Eq.(10), looks physically correct since if K increases (with M constant), f_n increases. If M increases with K constant, f_n decreases. These are the results we also find in practice.

We have seen that a solution to Eq. (9) is $y = A \sin(\omega t + \phi)$ or the same as Eq. (3). Hence we know that *any system that has a restoring force that is proportional to the displacement will have a displacement that is simple harmonic*. This is an alternative definition to that given in Section 3 for *simple harmonic motion*.

B. Free Vibration – Damped Many mechanical systems can be adequately described by the simple mass-spring system just discussed above. However, for some purposes it is necessary to include the effects of losses (sometimes called damping). This

Figure 6 Movement of damped simple system.

is normally done by including a viscous damper in the system (see Fig. 6). See Chapters 15 and 60 for further discussion on passive damping. With viscous or “coulomb” damping the friction or damping force F_d is assumed to be proportional to the velocity, dy/dt . If the constant of proportionality is R , then the damping force F_d on the mass is

$$F_d = -R \frac{dy}{dt} \quad (11)$$

and Eq. (9) becomes

$$-R \frac{dy}{dt} - Ky = M \frac{d^2y}{dt^2} \quad (12)$$

or equivalently

$$M\ddot{y} + R\dot{y} + Ky = 0 \quad (13)$$

where the dots represent single and double differentiation with respect to time.

The solution of Eq. (13) is most conveniently found by assuming a solution of the form: y is the real part of $Ae^{j\lambda t}$ where A is a complex number and λ is an arbitrary constant to be determined. By substituting $y = Ae^{j\lambda t}$ into Eq. (13) and assuming that the damping constant R is small, $R < (4MK)^{1/2}$ (which is true in most engineering applications), the solution is found that:

$$y = Ae^{-(R/2M)t} \sin(\omega_d t + \phi) \quad (14)$$

Here ω_d is known as the damped “natural” angular frequency:

$$\omega_d = \omega_n [1 - (R/2M)^2]^{1/2} \quad (15)$$

where ω_n is the undamped natural frequency $\sqrt{K/M}$. The motion described by Eq. (14) is plotted in Fig. 7.

Figure 7 Motion of a damped mass-spring system, $R < (4MK)^{1/2}$.

The amplitude of the motion decreases with time unlike that for undamped motion (Fig. 3). If the damping is increased until R equals $(4MK)^{1/2}$, the damping is then called critical, $R_{crit} = (4MK)^{1/2}$. In this case, if the mass in Fig. 6 is displaced, it gradually returns to its equilibrium position and the displacement never becomes negative. In other words, there is no oscillation or vibration. If $R > (4MK)^{1/2}$, the system is said to be overdamped.

The ratio of the damping constant R to the critical damping constant R_{crit} is called the damping ratio δ :

$$\delta = R/R_{crit} = R/(2M\omega) \quad (16a)$$

In most engineering cases the damping ratio, δ , in a structure is hard to predict and is of the order of 0.01 to 0.1. There are, however, several ways to measure damping experimentally. (See Chapters 15 and 60.)

C. Forced Vibration—Damped If a damped spring-mass system is excited by a simple harmonic force at some arbitrary angular forcing frequency ω (Fig. 8), we now obtain the equation of motion (16b):

$$M\ddot{y} + R\dot{y} + Ky = F e^{j(\omega t)} = |F| e^{j(\omega t + \phi)} \quad (16b)$$

The force F is normally written in the complex form for mathematical convenience. The real force acting is, of course, the real part of F or $|F| \cos(\omega t)$, where $|F|$ is the force amplitude.

Figure 8 Forced vibration of damped simple system.

If we assume a solution of the form $y = Ae^{j\omega t}$ then we obtain from Eq. (16b):

$$A = \frac{|F|}{j\omega R + K - M\omega^2} \quad (17)$$

We can write $A = |A|e^{j\alpha}$, where α is the phase angle between force and displacement. The phase, α , is not normally of much interest, but the amplitude of motion $|A|$ of the mass is. The amplitude of the

displacement is

$$|A| = \frac{|F|}{[\omega^2 R^2 + (K - M\omega^2)^2]^{1/2}} \quad (18)$$

This can be expressed in alternative form:

$$\frac{|A|}{|F|/K} = \frac{1}{[4\delta^2(\omega/\omega_n)^2 + (1 - (\omega/\omega_n)^2)^2]^{1/2}} \quad (19)$$

Equation (19) is plotted in Fig. 9. It is observed that if the forcing frequency ω is equal to the natural

Figure 9 Dynamic modification factor (DMF) for a damped simple system.

frequency of the structure, ω_n , or equivalently $f = f_n$, a condition called resonance, then the amplitude of the motion is proportional to $1/(2\delta)$. The ratio $|A|/(|F|/K)$ is sometimes called the *dynamic magnification factor* (DMF). The number $|F|/K$ is the *static deflection* the mass would assume if exposed to a *constant* nonfluctuating force $|F|$. If the damping ratio, δ , is small, the displacement amplitude A of a structure excited at its *natural* or *resonance* frequency is very high. For example, if a simple system has a damping ratio, δ , of 0.01, then its dynamic displacement amplitude is 50 times (when exposed to an oscillating force of $|F|$ N) its static deflection (when exposed to a static force of amplitude $|F|$ N), that is, DMF = 50. Situations such as this should be avoided in practice, wherever possible. For instance, if an oscillating force is present in some machine or structure, the frequency of the force should be moved away from the natural frequencies of the machine or structure, if possible, so that resonance is avoided. If the forcing frequency f is close to or coincides with a natural frequency f_n , large amplitude vibrations can occur with consequent vibration and noise problems and the potential of serious damage and machine malfunction.

The force on the idealized damped simple system will create a force on the base $F_B = R\dot{y} + Ky$. Substituting this into Eq. (16) and rearranging and finally comparing the amplitudes of the imposed force $|F|$ with the force transmitted to the base $|F_B|$ gives

$$\frac{|F_B|}{|F|} = \left[\frac{1 + 4\delta^2(\omega/\omega_n)^2}{4\delta^2(\omega/\omega_n)^2 + (1 - (\omega/\omega_n)^2)^2} \right]^{1/2} \quad (20)$$

Equation (20) is plotted in Fig. 10. The ratio $|F_B|/|F|$ is sometimes called the *force transmissibility* T_F . The force amplitude transmitted to the machine support base, F_B , is seen to be much greater than one, if the exciting frequency is at the system resonance frequency. The results in Eq. (20) and Fig. 10 have important applications to machinery noise problems that will be discussed again in detail in Chapter 54. Briefly, we can observe that these results can be utilized in designing vibration isolators for a machine. The natural frequency ω_n of a machine of mass M resting on its isolators of stiffness K and damping constant R must be made much less than the forcing frequency ω . Otherwise, large force amplitudes will be transmitted to the machine base. Transmitted forces will excite vibrations in machine supports and floors and walls of buildings, and the like, giving rise to additional noise radiation from these other areas. Chapter 59 gives a more complete discussion on vibration isolation.

5 PROPAGATION OF SOUND

5.1 Plane Sound Waves

The propagation of sound may be illustrated by considering gas in a tube with rigid walls and having a rigid piston at one end. The tube is assumed to be infinitely long in the direction away from the piston.

We shall assume that the piston is vibrating with simple harmonic motion at the left-hand side of the tube (see Fig. 11) and that it has been oscillating back and forth for some time. We shall only consider the piston motion and the oscillatory motion it induces in the fluid from when we start our clock. Let us choose to start our clock when the piston is moving with its maximum velocity to the right through its normal equilibrium position at $x = 0$. See the top of Fig. 11, at $t = 0$. As time increases from $t = 0$, the piston straight away starts slowing down with simple harmonic motion, so that it stops moving at $t = T/4$ at its maximum excursion to the right. The piston then starts moving to the left in its cycle of oscillation, and at $t = T/2$ it has reached its equilibrium position again and has a maximum velocity (the same as at $t = 0$) but now in the negative x direction. At $t = 3T/4$, the piston comes to rest again at its maximum excursion to the left. Finally at $t = T$ the piston reaches its equilibrium position at $x = 0$ with the same maximum velocity we imposed on it at $t = 0$. During the time T , the piston has undergone one complete cycle of oscillation. We assume that the piston continues vibrating and makes f oscillations each second, so that its frequency $f = 1/T$ (Hz).

As the piston moves backward and forward, the gas in front of the piston is set into motion. As we all know, the gas has mass and thus inertia and it is also compressible. If the gas is compressed into a smaller volume, its pressure increases. As the piston moves to the right, it compresses the gas in front of it, and as it moves to the left, the gas in front of it becomes rarified. When the gas is compressed, its pressure increases above atmospheric pressure, and, when it is rarified, its pressure decreases below atmospheric pressure. The pressure difference above or below the atmospheric pressure, p_0 , is known as the sound pressure, p , in the gas. Thus the sound pressure $p = p_{\text{tot}} - p_0$, where p_{tot} is the total pressure in the gas. If these pressure changes occurred at constant temperature, the fluid pressure would be directly proportional to its density, ρ , and so $p/\rho = \text{constant}$. This simple assumption was made by Sir Isaac Newton, who in 1660 was the first to try to predict the speed of sound. But we find that, in practice, regions of high and low pressure are sufficiently separated in space in the gas (see Fig. 11) so that heat cannot easily flow from one region to the other and that the adiabatic law, $p/\rho^\gamma = \text{constant}$, is more closely followed in nature.

As the piston moves to the right with maximum velocity at $t = 0$, the gas ahead receives maximum compression and maximum increase in density, and this simultaneously results in a maximum pressure increase. At the instant the piston is moving to the left with maximum negative velocity at $t = T/2$, the gas behind the piston, to the right, receives maximum rarefaction, which results in a maximum density and pressure decrease. These piston displacement and velocity perturbations are superimposed on the much greater random motion of the gas molecules (known as the Brownian motion). The mean speed of the molecular random motion in the gas depends on its absolute

Figure 10 Force transmissibility, T_F , for a damped simple system.

temperature. The disturbances induced in the gas are known as acoustic (or sound) disturbances. It is found that momentum and energy pulsations are transmitted from the piston throughout the whole region of the gas in the tube through molecular interactions (sometimes simply termed molecular collisions). The rate at which the motion is transmitted throughout the fluid depends upon its absolute temperature. The speed of transmission is known as the speed of sound, c_0 :

$$c_0 = (\gamma RT)^{1/2} \quad \text{metres/second}$$

where γ is the ratio of specific heats, R is the gas constant of the fluid in the tube, and T is the absolute temperature (K). A small region of fluid instantaneously enclosing a large number of gas molecules is known as a particle. The motion of the gas particles "mimics" the piston motion as it moves back and forth. The velocity of the gas particles (superimposed on the random Brownian motion of the molecules) depends upon the velocity of the piston as it moves back and forth and is completely unrelated to the speed of the sound propagation c_0 . For a given amplitude of vibration of

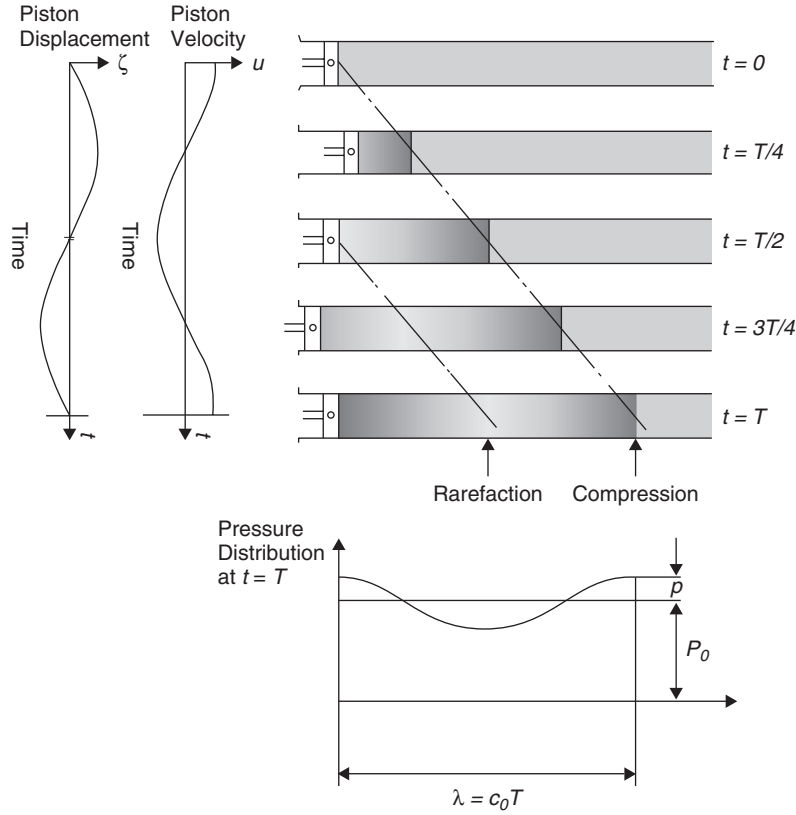

Figure 11 Schematic illustration of the sound pressure distribution created in a tube by a piston undergoing one complete simple harmonic cycle of operation in period T seconds.

the piston, A , we know from Eq. (4) that the velocity amplitude is ωA , which increases with frequency, and thus the piston only has a high-velocity amplitude if it is vibrated at high frequency.

Figure 11 shows the way that sound disturbances propagate along the tube from the oscillating piston. Dark regions in the tube indicate regions of high gas compression and high positive sound pressure. Light regions in the tube indicate regions of rarefaction and low negative sound pressure. Since the motion in the fluid is completely repeated periodically at one location and also is identically repeated spatially along the tube, we call the motion wave motion. At time $t = T$, the fluid disturbance, which was caused by the piston beginning at $t = 0$, will only have reached a distance $c_0 T$ along the tube. We call this location, the location of the *wave front* at the time T . Figure 11 shows that at distance $c_0 T$ along the tube, at which the motion starts to repeat itself. The distance $c_0 T$ is known as the wavelength λ (metres), and thus

$$\lambda = c_0 T \quad \text{metres}$$

Figure 11 shows the location of the wave front for different times and the sound pressure distribution in

the tube at $t = T$. The sound pressure distribution at some instant t is given by

$$p = P \cos(2\pi x / \lambda)$$

where P is the sound pressure amplitude (N/m^2). Since the piston is assumed to vibrate with simple harmonic motion with period T , its frequency of oscillation $f = 1/T$. Thus the wavelength λ (m) can be written

$$\lambda = c_0 / f$$

The sound pressure distribution, p (N/m^2), in the tube at any time t (s) can thus be written

$$p = P \cos[2\pi(x/\lambda - t/T)]$$

or

$$p = P \cos[(kx - \omega t)]$$

where $k = 2\pi/\lambda = \omega/c_0$ and $\omega = 2\pi f$. The parameter, k , is commonly known as the wavenumber, although the term wavelength parameter is better, since k has the dimensions of $1/\text{m}$.

5.2 Sound Pressure

With sound waves in a fluid such as air, the sound pressure at any point is the difference between the total pressure and normal atmospheric pressure. The sound pressure fluctuates with time and can be positive or negative with respect to the normal atmospheric pressure.

Sound varies in magnitude and frequency and it is normally convenient to give a single number measure of the sound by determining its time-averaged value. The time average of the sound pressure at any point in space, over a sufficiently long time, is zero and is of no interest or use. The time average of the square of the sound pressure, known as the mean square pressure, however, is not zero. If the sound pressure at any instant t is $p(t)$, then the mean square pressure, $\langle p^2(t) \rangle_t$, is the time average of the square of the sound pressure over the time interval T :

$$\langle p^2(t) \rangle_t = \frac{1}{T} \int_0^T p^2(t) dt \quad (21)$$

where $\langle \rangle_t$ denotes a time average.

It is usually convenient to use the square root of the mean square pressure:

$$p_{\text{rms}} = \sqrt{\langle p^2(t) \rangle_t} = \sqrt{\frac{1}{T} \int_0^T p^2(t) dt}$$

which is known as the root mean square (rms) sound pressure. This result is true for all cases of continuous sound time histories including noise and pure tones. For the special case of a pure tone sound, which is simple harmonic in time, given by $p = P \cos(\omega t)$, the root mean square sound pressure is

$$p_{\text{rms}} = P/\sqrt{2} \quad (22)$$

where P is the sound pressure amplitude.

5.3 Particle Velocity

As the piston vibrates, the gas immediately next to the piston must have the same velocity as the piston. A small element of fluid is known as a *particle*, and its velocity, which can be positive or negative, is known as the *particle velocity*. For waves traveling away from the piston in the positive x direction, it can be shown that the particle velocity, u , is given by

$$u = p/\rho c_0 \quad (23)$$

where ρ = fluid density (kg/m³) and c_0 = speed of sound (m/s).

If a wave is reflected by an obstacle, so that it is traveling in the negative x direction, then

$$u = -p/\rho c_0 \quad (24)$$

The negative sign results from the fact that the sound pressure is a scalar quantity, while the particle velocity is a vector quantity. These results are true for any type of plane sound waves, not only for sinusoidal waves.

5.4 Sound Intensity

The intensity of sound, I , is the time-averaged sound energy that passes through unit cross-sectional area in unit time. For a plane progressive wave, or far from any source of sound (in the absence of reflections):

$$I = p_{\text{rms}}^2/\rho c_0 \quad (25)$$

where ρ = the fluid density (kg/m³) and c_0 = speed of sound (m/s).

In the general case of sound propagation in a three-dimensional field, the sound intensity is the (net) flow of sound energy in unit time flowing through unit cross-sectional area. The intensity has magnitude and direction

$$I = pu_r = \langle p \cdot u_r \rangle_t = \frac{1}{T} \int_0^T p \cdot u_r dt \quad (26)$$

where p is the total fluctuating sound pressure, and u_r is the total fluctuating sound particle velocity in the r direction at the measurement point. The total sound pressure p and particle velocity u_r include the effects of incident and reflected sound waves.

5.5 Energy Density

Consider the case again of the oscillating piston in Fig. 11. We shall consider the sound energy that is produced by the oscillating piston, as it flows along the tube from the piston. We observe that the wavefront and the sound energy travel along the tube with velocity c_0 metres/second. Thus after 1 s, a column of fluid of length c_0 m contains all of the sound energy provided by the piston during the previous second. The total amount of energy E in this column equals the time-averaged sound intensity multiplied by the cross-sectional area S , which is from Eq. (22):

$$E = SI = Sp_{\text{rms}}^2/\rho c_0 \quad (27)$$

The sound per energy unit volume is known as the energy density ϵ ,

$$\epsilon = [Sp_{\text{rms}}^2/\rho c_0]/c_0 S = p_{\text{rms}}^2/\rho c_0^2 \quad (28)$$

This result in Eq. (28) can also be shown to be true for other acoustic fields as well, as long as the total sound pressure is used in Eq. (28), and provided the location is not very close to a sound source.

5.6 Sound Power

Again in the case of the oscillating piston, we will consider the sound power radiated by the piston into the tube. The sound power radiated by the piston, W , is

$$W = SI \quad (29)$$

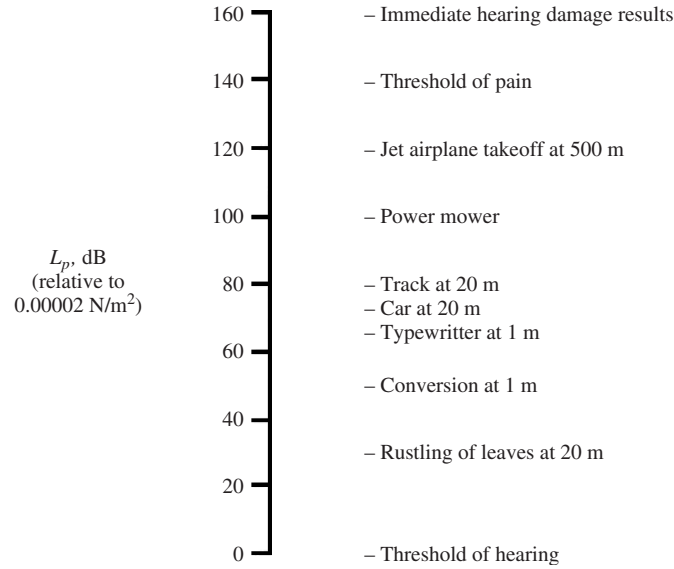

Figure 12 Some typical sound pressure levels, L_p .

But from Eqs. (23) and (25) the power is

$$W = S(p_{\text{rms}}u_{\text{rms}}) \quad (29a)$$

and close to the piston, the rms particle velocity, u_{rms} , must be equal to the rms piston velocity. From Eq. (29a), we can write

$$W = S\rho c_0 v_{\text{rms}}^2 = 4\pi r^2 \rho c_0 v_{\text{rms}}^2 \quad (30)$$

where r is the piston and duct radius, and v_{rms} is the rms velocity of the piston.

6 DECIBELS AND LEVELS

The range of sound pressure magnitudes and sound powers of sources experienced in practice is very large. Thus, logarithmic rather than linear measures are often used for sound pressure and sound power. The most common measure of sound is the *decibel*. Decibels are also used to measure vibration, which can have a similar large range of magnitudes. The decibel represents a relative measurement or ratio. Each quantity in decibels is expressed as a ratio relative to a *reference sound pressure*, *sound power*, or *sound intensity*, or in the case of vibration relative to a *reference displacement*, *velocity*, or *acceleration*. Whenever a quantity is expressed in decibels, the result is known as a *level*.

The decibel (dB) is the ratio R_1 given by

$$\log_{10} R_1 = 0.1 \quad 10 \log_{10} R_1 = 1 \text{ dB} \quad (31)$$

Thus, $R_1 = 10^{0.1} = 1.26$. The decibel is seen to represent the ratio 1.26. A larger ratio, the *bel*, is sometimes used. The bel is the ratio R_2 given by

$\log_{10} R_2 = 1$. Thus, $R_2 = 10^1 = 10$. The bel represents the ratio 10 and is thus much larger than a decibel.

6.1 Sound Pressure Level

The sound pressure level L_p is given by

$$\begin{aligned} L_p &= 10 \log_{10} \left(\frac{\langle p^2 \rangle_t}{p_{\text{ref}}^2} \right) = 10 \log_{10} \left(\frac{p_{\text{rms}}^2}{p_{\text{ref}}^2} \right) \\ &= 20 \log_{10} \left(\frac{p_{\text{rms}}}{p_{\text{ref}}} \right) \text{ dB} \end{aligned} \quad (32)$$

where p_{ref} is the reference pressure, $p_{\text{ref}} = 20 \mu\text{Pa} = 0.00002 \text{ N/m}^2 (= 0.0002 \mu\text{bar})$ for air. This reference pressure was originally chosen to correspond to the quietest sound (at 1000 Hz) that the average young person can hear. The sound pressure level is often abbreviated as SPL. Figure 12 shows some sound pressure levels of typical sounds.

6.2 Sound Power Level

The sound power level of a source, L_W , is given by

$$L_W = 10 \log_{10} \left(\frac{W}{W_{\text{ref}}} \right) \text{ dB} \quad (33)$$

where W is the sound power of a source and $W_{\text{ref}} = 10^{-12} \text{ W}$ is the reference sound power.

Some typical sound power levels are given in Fig. 13.

6.3 Sound Intensity Level

The sound intensity level L_I is given by

$$L_I = 10 \log_{10} \left(\frac{I}{I_{\text{ref}}} \right) \text{ dB} \quad (34)$$

Figure 13 Some typical sound power levels, L_w .

where I is the component of the sound intensity in a given direction and $I_{\text{ref}} = 10^{-12} \text{ W/m}^2$ is the reference sound intensity.

6.4 Combination of Decibels

If the sound pressures p_1 and p_2 at a point produced by two independent sources are combined, the mean square pressure is

$$\begin{aligned}
 p_{\text{rms}}^2 &= \frac{1}{T} \int_0^T (p_1 + p_2)^2 dt = \langle p_1^2 + 2p_1p_2 + p_2^2 \rangle_t \\
 &= \langle p_1^2 \rangle_t + \langle p_2^2 \rangle_t + 2\langle p_1p_2 \rangle_t \equiv \overline{p_1^2} + \overline{p_2^2} \\
 &\quad + 2\overline{p_1p_2}, \quad (35)
 \end{aligned}$$

where $\langle \rangle_t$ and the overbar indicate the time average $\frac{1}{T} \int_0^T \langle \rangle dt$.

Except for some special cases, such as two pure tones of the same frequency or the sounds from two correlated sound sources, the cross term $2\langle p_1p_2 \rangle_t$ disappears if $T \rightarrow \infty$. Then in such cases, the mean square sound pressures $\overline{p_1^2}$ and $\overline{p_2^2}$ are additive, and the total mean square sound pressure at some point in space, if they are completely independent noise sources, may be determined using Eq. (35a).

$$p_{\text{rms}}^2 = \overline{p_1^2} + \overline{p_2^2} \quad (35a)$$

Let the two mean square pressure contributions to the total noise be $p_{\text{rms}1}^2$ and $p_{\text{rms}2}^2$ corresponding to sound pressure levels L_{p1} and L_{p2} , where $L_{p2} = L_{p1} - \Delta$. The total sound pressure level is given by

the sum of the individual contributions in the case of uncorrelated sources, and the total sound pressure level is given by forming the total sound pressure level by taking logarithms of Eq. (35a)

$$\begin{aligned}
 L_{pt} &= 10 \log[(p_{\text{rms}1}^2 + p_{\text{rms}2}^2)/p_{\text{ref}}^2] \\
 &= 10 \log(10^{L_{p1}/10} + 10^{L_{p2}/10}) \\
 &= 10 \log(10^{L_{p1}/10} + 10^{(L_{p1}-\Delta)/10}) \\
 &= 10 \log[10^{L_{p1}/10}(1 + 10^{-\Delta/10})] \\
 &= L_{p1} + 10 \log(1 + 10^{-\Delta/10}) \quad (35b)
 \end{aligned}$$

where, L_{pT} = combined sound pressure level due to both sources

L_{p1} = greater of the two sound pressure level contributions

Δ = difference between the two contributions, all in dB

Equation (35b) is presented in Fig. 14.

Example 1 If two independent noise sources each create sound pressure levels operating on their own of 80 dB, at a certain point, what is the total sound pressure level? *Answer:* The difference in levels is 0 dB; thus the total sound pressure level is $80 + 3 = 83 \text{ dB}$.

Example 2 If two independent noise sources have sound power levels of 70 and 73 dB, what is the total level? *Answer:* The difference in levels is 3 dB; thus the total sound power level is $73 + 1.8 = 74.8 \text{ dB}$.

Figure 14 and these two examples do *not* apply to the case of two pure tones of the same frequency.

Figure 14 Diagram for combination of two sound pressure levels or two sound power levels of uncorrelated sources.

Note: For the special case of two pure tones of the same amplitude and frequency, if $p_1 = p_2$ (and the sound pressures are in phase at the point in space of the measurement):

$$L_{p_{\text{total}}} = 10 \log \left[\frac{1}{T} \int_0^T (p_1 + p_2)^2 dt \right] \\ = L_{p_1} + 10 \log 4 \equiv L_{p_2} + 6 \text{ dB} \quad (36)$$

Example 3 If $p_1 = p_2 = 1$ Pa and the two sound pressures are of the same amplitude and frequency and in phase with each other, then the total sound pressure level

$$L_p(\text{total}) = 20 \log \left[\frac{2}{20 \times 10^{-6}} \right] = 100 \text{ dB}$$

Example 4 If $p_1 = p_2 = 1$ Pa and the two sound pressures are of the same amplitude and frequency, but in opposite phase with each other, then the total sound pressure level

$$L_p(\text{total}) = 20 \log \left[\frac{0}{20 \times 10^{-6}} \right] = -\infty \text{ dB}$$

For such a case as in Example 1 above, for pure-tone sounds, instead of 83 dB, the total sound pressure level can range anywhere between 86 dB (for in-phase sound pressures) and $-\infty$ dB (for out-of-phase sound pressures). For the Example 2 above, the total sound power radiated by the two pure-tone sources depends on the phasing and separation distance.

7 HUMAN HEARING

Human hearing is most sensitive at about 4000 Hz. We can hear sound down to a frequency of about 15 or 16 Hz and up to about 15,000 to 16,000 Hz. However, at low frequency below about 200 Hz, we cannot hear sound at all well, unless the sound pressure level is quite high. See Chapters 19 and 20 for more details. Normal speech is in the range of about 100 to 4000 Hz with vowels mostly in the low- to medium-frequency range and consonants mostly in the high-frequency range. See Chapter 22. Music has a larger frequency range and can be at much higher sound pressure levels than the human voice. Figure 15 gives an idea of the approximate frequency and sound pressure level boundaries of speech, music, and the audible range

of human hearing. The lower boundary in Fig. 15 is called the threshold of hearing since sounds below this level cannot be heard by the average young person. The upper boundary is called the threshold of feeling since sounds much above this boundary can cause unpleasant sensations in the ear and even pain and, at high enough sound pressure levels, immediate damage to the hearing mechanism. See Chapter 21.

8 FREQUENCY ANALYSIS

Sound signals can be combined, but they can also be broken down into frequency components as shown by Fourier over 200 years ago. The ear seems to work as a frequency analyzer. We also can make instruments to analyze sound signals into frequency components.

Frequency analysis is commonly carried out using (a) constant frequency band filters and (b) constant percentage filters. The constant percentage filter (usually one-octave or one-third-octave band types) most parallels the way the human auditory system analyzes sound and, although digital processing has mostly overtaken analog processing of signals, it is still frequently used. See Chapters 40, 41, and 42 for more details about filters, signal processing, and data analysis.

The following symbol notation is used in Sections 8.1 and 8.2: f_L and f_U are the lower and upper cutoff frequencies, and f_C and Δf are the band center frequency and the frequency bandwidth, respectively. Thus $\Delta f = f_U - f_L$. See Fig. 16.

8.1 One-Octave Bands

For one-octave bands, the cutoff frequencies f_L and f_U are defined as follows:

$$f_L = f_C / \sqrt{2} \\ f_U = \sqrt{2} f_C$$

The center frequency (or geometric mean) is

$$f_C = \sqrt{f_L f_U}$$

Thus

$$f_U / f_L = 2$$

The bandwidth Δf is given by

$$\Delta f = f_U - f_L = f_C(\sqrt{2} - 1/\sqrt{2}) = f_C/\sqrt{2}$$

Figure 15 Sound pressure level versus frequency for the audible range, typical music range, and range of speech.

Figure 16 Typical frequency response of a filter of center frequency f_C and upper and lower cutoff frequencies, f_U and f_L .

so

$$\Delta f \approx 70\%(f_C)$$

8.2 One-Third-Octave Bands

For one-third-octave bands the cutoff frequencies, f_L and f_U , are defined as follows:

$$f_L = f_C / \sqrt[6]{2} = f_C / 2^{1/6}$$

$$f_U = f_C 2^{1/6}$$

The center frequency (geometric mean) is given by

$$f_C = \sqrt{f_L f_U}$$

Thus

$$f_U / f_L = 2^{1/3}$$

The bandwidth Δf is given by

$$\Delta f = f_U - f_L = f_C (2^{1/6} - 2^{-1/6})$$

so

$$\Delta f \approx 23\%(f_C)$$

NOTE

1. The center frequencies of one-octave bands are related by 2, and 10 frequency bands are used to cover the human hearing range. They have center frequencies of 31.5, 63, 125, 250, 500, 1000, 2000, 4000, 8000, 16,000 Hz.
2. The center frequencies of one-third octave bands are related by $2^{1/3}$ and 10 cover a decade of frequency, and thus 30 frequency bands are used to cover the human hearing range: 20, 25, 31.5, 40, 50, 63, 80, 100, 125, 160, ... 16,000 Hz.

9 FREQUENCY WEIGHTING (A, B, C, D)

Other filters are often used to simulate the hearing system of humans. The relative responses of A-, B-, C-, and D-weighting filters are shown in Fig. 17. The most commonly used is the A-weighting filter. These filter weightings are related to human response to pure tone sounds, although they are often used to give an approximate evaluation of the loudness of noise as well. Chapter 21 discusses the loudness of sound in more detail.

10 EQUIVALENT SOUND PRESSURE LEVEL (L_{eq})

The equivalent sound pressure level, L_{eq} , has become very frequently used in many countries in the last 20 to 25 years to evaluate industrial noise, community noise near airports, railroads, and highways. See Chapter 34

Figure 17 Frequency weightings.

for more details. The equivalent sound pressure level is defined by

$$L_{eq} = 10 \log \left[\frac{\overline{p_{rms}^2}}{p_{ref}^2} \right] = 10 \log \frac{1}{T} \int_0^T 10^{L(t)/10} dt$$

$$= 10 \log \frac{1}{N} \sum_{i=1}^N 10^{L_i/10} \quad (37)$$

The averaging time T can be, for example, 1 h, 8 h, 1 day, 1 week, 1 month, and so forth. $L(t)$ is the short-time average. See Fig. 18a. L_i can be a set of short-time averages for L_p over set periods. If the sound pressure levels, L_i , are values averaged over constant time periods such as one hour, then they can be summed as in Eq. (37). See Fig. 18b. The sound pressure signal is normally filtered with an A-weighting filter.

11 DAY-NIGHT SOUND PRESSURE LEVEL(L_{dn})

In some countries, penalties are made for noise made at night. For instance in the United States the so-called day-night level is defined by

$$L_{dn} = 10 \log \left[\frac{1}{24} \left\{ \int_{07:00}^{22:00} 10^{L_p/10} dt + \int_{22:00}^{07:00} 10^{(L_p+10)/10} dt \right\} \right] \quad (38)$$

The day-night level L_{dn} has a 10-dB penalty applied between the hours of 22:00 and 07:00. See Eq. (38).

The sound pressure level L_p readings (short time) used in Eq. (38) are normally A-weighted. The day-night descriptor can also be written

$$L_{dn} = 10 \log \left[\frac{1}{24} \{ 15 \times 10^{L_{eqd}/10} + 9 \times 10^{(L_{eqn}+10)/10} \} \right] \quad (39)$$

where L_{eqd} is the A-weighted daytime equivalent sound pressure level (from 07:00 to 22:00) and L_{eqn} is the night-time A-weighted sound pressure level (from 22:00 to 07:00).

12 DAY-EVENING-NIGHT SOUND PRESSURE LEVEL(L_{den})

In some countries, separate penalties are made for noise made during evening and night periods. For instance, the so-called day-evening-night level is defined by

$$L_{den} = 10 \log \left[\frac{1}{24} \left\{ \int_{07:00}^{19:00} 10^{L_p/10} dt + \int_{19:00}^{22:00} 10^{(L_p+5)/10} dt + \int_{22:00}^{07:00} 10^{(L_p+10)/10} dt \right\} \right] \quad (40)$$

The day-evening-night level L_{den} has a 5-dB penalty applied during the evening hours (here shown as 19:00 to 22:00) and a 10-dB penalty applied between the hours of 22:00 and 07:00. See Eq. (40). Local jurisdictions can set the evening period to be different

Figure 18 Equivalent sound pressure level.

from 19:00 to 22:00, if they wish to do so for their community.

PART I

**FUNDAMENTALS OF
ACOUSTICS AND NOISE**

CHAPTER 2

THEORY OF SOUND – PREDICTIONS AND MEASUREMENT

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

The fluid mechanics equations, from which the acoustics equations and results may be derived, are quite complicated. However, because most acoustical phenomena involve very small perturbations from steady-state conditions, it is possible to make significant simplifications to these fluid equations and to linearize them. The results are the equations of linear acoustics. The most important equation, the wave equation, is presented in this chapter together with some of its solutions. Such solutions give the sound pressure explicitly as functions of time and space, and the general approach may be termed the wave acoustics approach. This chapter presents some of the useful results of this approach but also briefly discusses some of the other alternative approaches, sometimes termed ray acoustics and energy acoustics that are used when the wave acoustics approach becomes too complicated.

The first purpose of this chapter is to present some of the most important acoustics formulas and definitions, without derivation, which are used in the chapters following in Part I and in many of the other chapters of this handbook. The second purpose is to make some helpful comments about the chapters that follow in Part I and about other chapters as seems appropriate.

2 WAVE MOTION

Some of the basic concepts of acoustics and sound wave propagation used in Part I and also throughout the rest of this book are discussed here. For further discussion of some of these basic concepts and/or a more advanced mathematical treatment of some of them, the reader is referred to Chapters 3, 4, and 5 and later chapters in this book. The chapters in Part I of the *Handbook of Acoustics*¹ and other texts^{2–12} are also useful for further discussion on fundamentals and applications of the theory of noise and vibration problems.

Wave motion is easily observed in the waves on stretched strings and as ripples on the surface of water. Waves on strings and surface water waves are very similar to sound waves in air (which we cannot see), but there are some differences that are useful to discuss. If we throw a stone into a calm lake, we observe that the water waves (*ripples*) travel out from the point where the stone enters the water. The ripples spread out circularly from the source at the

wave speed, which is independent of the wave height. Somewhat like the water ripples, sound waves in air travel at a constant speed, which is proportional to the square root of the absolute temperature and is almost independent of the sound wave strength. The wave speed is known as the speed of sound. Sound waves in air propagate by transferring momentum and energy between air particles. Sound wave motion in air is a disturbance that is imposed onto the random motion of the air molecules (known as Brownian motion). The mean speed of the molecular random motion and rate of molecular interaction increases with the absolute temperature of the gas. Since the momentum and sound energy transfer occurs through the molecular interaction, the sound wave speed is dependent solely upon the absolute temperature of the gas and *not* upon the strength of the sound wave disturbance. There is no net flow of air away from a source of sound, just as there is no net flow of water away from the source of water waves. Of course, unlike the waves on the surface of a lake, which are circular or two dimensional, sound waves in air in general are spherical or three dimensional.

As water waves move away from a source, their curvature decreases, and the *wavefronts* may be regarded almost as straight lines. Such waves are observed in practice as *breakers* on the seashore. A similar situation occurs with sound waves in the atmosphere. At large distances from a source of sound, the spherical wavefront curvature decreases, and the wavefronts may be regarded almost as plane surfaces.

Plane sound waves may be defined as waves that have the same acoustical properties at any position on a plane surface drawn perpendicular to the direction of propagation of the wave. Such plane sound waves can exist and propagate along a long straight tube or duct (such as an air-conditioning duct). In such a case, the waves propagate in a direction along the duct axis and the plane wave surfaces are perpendicular to this direction (and are represented by duct cross sections). Such waves in a duct are one dimensional, like the waves traveling along a long string or rope under tension (or like the ocean breakers described above).

Although there are many similarities between one-dimensional sound waves in air, waves on strings, and surface water waves, there are some differences. In a fluid such as air, the fluid particles vibrate back and forth in the same direction as the direction of wave propagation; such waves are known as longitudinal,

compressional, or sound waves. On a stretched string, the particles vibrate at right angles to the direction of wave propagation; such waves are usually known as transverse waves. The surface water waves described are partly transverse and partly longitudinal, with the complication that the water particles move up and down and back and forth horizontally. (This movement describes elliptical paths in shallow water and circular paths in deep water. The vertical particle motion is much greater than the horizontal motion for shallow water, but the two motions are equal for deep water.) The water wave direction is, of course, horizontal.

Surface water waves are not compressional (like sound waves) and are normally termed surface gravity waves. Unlike sound waves, where the wave speed is independent of frequency, long wavelength surface water waves travel faster than short wavelength waves, and thus water wave motion is said to be dispersive. Bending waves on beams, plates, cylinders, and other engineering structures are also dispersive (see Chapter 10). There are several other types of waves that can be of interest in acoustics: shear waves, torsional waves, and boundary waves (see Chapter 12 in the *Encyclopedia of Acoustics*¹³), but the discussion here will concentrate on sound wave propagation in fluids.

3 PLANE SOUND WAVES

If a disturbance in a thin cross-sectional element of fluid in a duct is considered, a mathematical description of the motion may be obtained by assuming that (1) the amount of fluid in the element is conserved, (2) the net longitudinal force is balanced by the inertia of the fluid in the element, (3) the compressive process in the element is adiabatic (i.e., there is no flow of heat in or out of the element), and (4) the undisturbed fluid is stationary (there is no fluid flow). Then the following equation of motion may be derived:

$$\frac{\partial^2 p}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (1)$$

where p is the sound pressure, x is the coordinate, and t is the time.

This equation is known as the one-dimensional equation of motion, or acoustic wave equation. Similar wave equations may be written if the sound pressure p in Eq. (1) is replaced with the particle displacement ξ , the particle velocity u , condensation s , fluctuating density ρ' , or the fluctuating absolute temperature T' . The derivation of these equations is in general more complicated. However, the wave equation in terms of the sound pressure in Eq. (1) is perhaps most useful since the sound pressure is the easiest acoustical quantity to measure (using a microphone) and is the acoustical perturbation we sense with our ears. It is normal to write the wave equation in terms of sound pressure p , and to derive the other variables, ξ , u , s , ρ' , and T' from their relations with the sound pressure p .⁴ The sound pressure p is the acoustic pressure

perturbation or fluctuation about the time-averaged, or undisturbed, pressure p_0 .

The speed of sound waves c is given for a perfect gas by

$$c = (\gamma RT)^{1/2} \quad (2)$$

The speed of sound is proportional to the square root of the absolute temperature T . The ratio of specific heats γ and the gas constant R are constants for any particular gas. Thus Eq. (2) may be written as

$$c = c_0 + 0.6T_c \quad (3)$$

where, for air, $c_0 = 331.6$ m/s, the speed of sound at 0°C , and T_c is the temperature in degrees Celsius. Note that Eq. (3) is an approximate formula valid for T_c near room temperature. The speed of sound in air is almost completely dependent on the air temperature and is almost independent of the atmospheric pressure. For a complete discussion of the speed of sound in fluids, see Chapter 5 in the *Handbook of Acoustics*.¹

A solution to (1) is

$$p = f_1(ct - x) + f_2(ct + x) \quad (4)$$

where f_1 and f_2 are arbitrary functions such as sine, cosine, exponential, log, and so on. It is easy to show that Eq. (4) is a solution to the wave equation (1) by differentiation and substitution into Eq. (1). Varying x and t in Eq. (4) demonstrates that $f_1(ct - x)$ represents a wave traveling in the positive x direction with wave speed c , while $f_2(ct + x)$ represents a wave traveling in the negative x direction with wave speed c (see Fig. 1).

The solution given in Eq. (4) is usually known as the *general solution* since, in principle, any type of sound waveform is possible. In practice, sound waves are usually classified as impulsive or steady in time. One particular case of a steady wave is of considerable importance. Waves created by sources vibrating sinusoidally in time (e.g., a loudspeaker, a piston, or a more complicated structure vibrating with a discrete angular frequency ω) both in time t and space x in a sinusoidal manner (see Fig. 2):

$$p = p_1 \sin(\omega t - kx + \phi_1) + p_2 \sin(\omega t + kx + \phi_2) \quad (5)$$

Figure 1 Plane waves of arbitrary waveform.

At any point in space, x , the sound pressure p is simple harmonic in time. The first expression on the right of Eq. (5) represents a wave of amplitude p_1 traveling in the positive x direction with speed c , while the second expression represents a wave of amplitude p_2 traveling in the negative x direction. The symbols ϕ_1 and ϕ_2 are phase angles, and k is the *acoustic wavenumber*. It is observed that the wavenumber $k = \omega/c$ by studying the ratio of x and t in Eqs. (4) and (5). At some instant t the sound pressure pattern is sinusoidal in space, and it repeats itself each time kx is increased by 2π . Such a repetition is called a wavelength λ . Hence, $k\lambda = 2\pi$ or $k = 2\pi/\lambda$. This gives $\omega/c = 2\pi/\lambda = 2\pi/\lambda$, or

$$\lambda = \frac{c}{f} \quad (6)$$

The wavelength of sound becomes smaller as the frequency is increased. In air, at 100 Hz, $\lambda \approx 3.5 \text{ m} \approx 10 \text{ ft}$. At 1000 Hz, $\lambda \approx 0.35 \text{ m} \approx 1 \text{ ft}$. At 10,000 Hz, $\lambda \approx 0.035 \text{ m} \approx 0.1 \text{ ft} \approx 1 \text{ in}$.

At some point x in space, the sound pressure is sinusoidal in time and goes through one complete cycle when ω increases by 2π . The time for a cycle is called the period T . Thus, $\omega T = 2\pi$, $T = 2\pi/\omega$, and

$$T = \frac{1}{f} \quad (7)$$

4 IMPEDANCE AND SOUND INTENSITY

We see that for the one-dimensional propagation considered, the sound wave disturbances travel with a constant wave speed c , although there is no net, time-averaged movement of the air particles. The air particles oscillate back and forth in the direction of wave propagation (x axis) with velocity u . We may show that for any plane wave traveling in the positive x direction at any instant

$$\frac{p}{u} = \rho c \quad (8)$$

and for any plane wave traveling in the negative x direction

$$\frac{p}{u} = -\rho c \quad (9)$$

Figure 2 Simple harmonic plane waves.

The quantity ρc is known as the characteristic impedance of the fluid, and for air, $\rho c = 428 \text{ kg/m}^2 \text{ s}$ at 0°C and $415 \text{ kg/m}^2 \text{ s}$ at 20°C .

The *sound intensity* is the rate at which the sound wave does work on an imaginary surface of unit area in a direction perpendicular to the surface. Thus, it can be shown that the *instantaneous* sound intensity in the x direction, I , is obtained by multiplying the *instantaneous* sound pressure p by the *instantaneous* particle velocity in the x direction, u . Therefore

$$I = pu \quad (10)$$

and for a plane wave traveling in the positive x direction this becomes

$$I = \frac{p^2}{\rho c} \quad (11)$$

The time-averaged sound intensity for a plane wave traveling in the positive x direction, $\langle I \rangle_t$, is given as

$$\langle I \rangle_t = \frac{\langle p^2 \rangle_t}{\rho c} \quad (12)$$

and for the special case of a sinusoidal (pure-tone) sound wave

$$\langle I \rangle_t = \frac{\langle p^2 \rangle_t}{\rho c} = \frac{\hat{p}^2}{2\rho c} \quad (13)$$

where \hat{p} is the sound pressure amplitude, and the mean-square sound pressure is thus $\langle p^2 \rangle_t = p_{\text{rms}}^2 = \frac{1}{2}\hat{p}^2$.

We note, in general, for sound propagation in three dimensions that the instantaneous sound intensity \mathbf{I} is a vector quantity equal to the product of the sound pressure and the instantaneous particle velocity \mathbf{u} . Thus \mathbf{I} has magnitude and direction. The vector intensity \mathbf{I} may be resolved into components \mathbf{I}_x , \mathbf{I}_y , and \mathbf{I}_z . For a more complete discussion of sound intensity and its measurement see Chapter 45 and Chapter 156 in the *Handbook of Acoustics*¹ and the book by Fahy.⁹

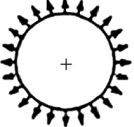

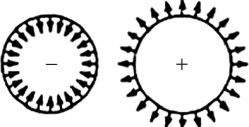

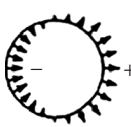

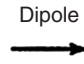

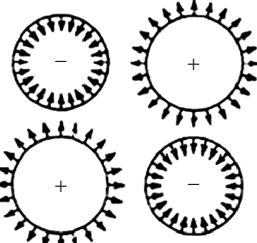

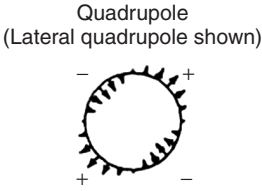

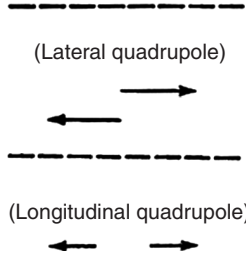

5 THREE-DIMENSIONAL WAVE EQUATION

In most sound fields, sound propagation occurs in two or three dimensions. The three-dimensional version of Eq. (1) in Cartesian coordinates is

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (14)$$

This equation is useful if sound wave propagation in rectangular spaces such as rooms is being considered. However, it is helpful to recast Eq. (14) in spherical coordinates if sound propagation from sources of sound in free space is being considered. It is a simple mathematical procedure to transform Eq. (14) into spherical coordinates, although the resulting equation

Table 1 Models of Idealized Spherical Sources: Monopole, Dipole, and Quadrupole^a

Monopole Distribution Representation	Velocity Distribution on Spherical Surface	Oscillating Sphere Representation	Oscillating Force Model
<p>Monopole</p> 			
<p>Dipole</p> 	<p>Dipole</p> 	<p>Dipole</p> 	<p>Dipole</p> 
<p>Quadrupole (Lateral quadrupole shown)</p> 	<p>Quadrupole (Lateral quadrupole shown)</p> 	<p>Quadrupole (Lateral quadrupole shown)</p> 	<p>Quadrupole</p>  <p>(Lateral quadrupole)</p> <p>(Longitudinal quadrupole)</p>

^a For simple harmonic sources, after one half-period the velocity changes direction; positive sources become negative and vice versa, and forces reverse direction with dipole and quadrupole force models.

is quite complicated. However, for propagation of sound waves from a spherically symmetric source (such as the idealized case of a pulsating spherical balloon known as an omnidirectional or monopole source) (Table 1), the equation becomes quite simple (since there is no angular dependence):

$$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial p}{\partial r} \right) - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (15a)$$

After some algebraic manipulation Eq. (15a) can be written as

$$\frac{\partial^2(rp)}{\partial r^2} - \frac{1}{c^2} \frac{\partial^2(rp)}{\partial t^2} = 0 \quad (15b)$$

Here, r is the distance from the origin and p is the sound pressure at that distance.

Equation (15a) is identical in form to Eq. (1) with p replaced by rp and x by r . The general and simple harmonic solutions to Eq. (15a) are thus the same as Eqs. (4) and (5) with p replaced by rp and x with r . The general solution is

$$rp = f_1(ct - r) + f_2(ct + r) \quad (16)$$

or

$$p = \frac{1}{r} f_1(ct - r) + \frac{1}{r} f_2(ct + r) \quad (17)$$

where f_1 and f_2 are arbitrary functions. The first term on the right of Eq. (17) represents a wave traveling outward from the origin; the sound pressure p is seen to be inversely proportional to the distance r . The second term in Eq. (17) represents a sound wave traveling inward toward the origin, and in most practical cases such waves can be ignored (if reflecting surfaces are absent).

The simple harmonic (pure-tone) solution of Eq. (15) is

$$p = \frac{A_1}{r} \sin(\omega t - kr + \phi_1) + \frac{A_2}{r} \sin(\omega t + kr + \phi_2). \quad (18)$$

We may now write that the constants A_1 and A_2 may be written as $A_1 = \hat{p}_1 r$ and $A_2 = \hat{p}_2 r$, where \hat{p}_1 and \hat{p}_2 are the sound pressure amplitudes at unit distance (usually m) from the origin.

6 SOURCES OF SOUND

The second term on the right of Eq. (18), as before, represents sound waves traveling inward to the origin

and is of little practical interest. However, the first term represents simple harmonic waves of angular frequency ω traveling outward from the origin, and this may be rewritten as⁶

$$p = \frac{\rho c k Q}{4\pi r} \sin(\omega t - kr + \phi_1) \quad (19)$$

where Q is termed the *strength of an omnidirectional (monopole) source* situated at the origin, and $Q = 4\pi A_1 / \rho c k$. The mean-square sound pressure p_{rms}^2 may be found⁶ by time averaging the square of Eq. (19) over a period T :

$$p_{\text{rms}}^2 = \frac{(\rho c k)^2 Q^2}{32\pi^2 r^2} \quad (20)$$

From Eq. (20), the mean-square pressure is seen to vary with the inverse square of the distance r from the origin of the source for such an idealized omnidirectional point sound source everywhere in the sound field. Again, this is known as the *inverse square law*. If the distance r is doubled, the sound pressure level [see Eq. (29) in Chapter 1] decreases by $20 \log_{10}(2) = 20(0.301) = 6$ dB. If the source is idealized as a sphere of radius a pulsating with a simple harmonic velocity amplitude U , we may show that Q has units of volume flow rate (cubic metres per second). If the source radius is small in wavelengths so that $a \leq \lambda$ or $ka \leq 2\pi$, then we can show that the strength $Q = 4\pi a^2 U$.

Many sources of sound are not like the simple omnidirectional monopole source just described. For example, an un baffled loudspeaker produces sound both from the back and front of the loudspeaker. The sound from the front and the back can be considered as two sources that are 180° out of phase with each other. This system can be modeled^{6,9} as two out-of-phase monopoles of source strength Q separated by a distance l . Provided $l \ll \lambda$, the sound pressure produced by such a dipole system is

$$p = \frac{\rho c k Q l \cos \theta}{4\pi r} \left[\frac{1}{r} \sin(\omega t - kr + \phi) + k \cos(\omega t - kr + \phi) \right] \quad (21)$$

where θ is the angle measured from the axis joining the two sources (the loudspeaker axis in the practical case). Unlike the monopole, the dipole field is not omnidirectional. The sound pressure field is directional. It is, however, symmetric and shaped like a figure-eight with its lobes on the dipole axis, as shown in Fig. 7b.

The sound pressure of a dipole source has near-field and far-field regions that exhibit similar behaviors to the particle velocity near-field and far-field regions of a monopole. Close to the source (the near field), for some fixed angle θ , the sound pressure falls

off rapidly, $p \propto 1/r^2$, while far from the source (the far field $kr \geq 1$), the pressure falls off more slowly, $p \propto 1/r$. In the near field, the sound pressure level decreases by 12 dB for each doubling of distance r . In the far field the decrease in sound pressure level is only 6 dB for doubling of r (like a monopole). The phase of the sound pressure also changes with distance r , since close to the source the sine term dominates and far from the source the cosine term dominates. The particle velocity may be obtained from the sound pressure [Eq. (21)] and use of Euler's equation [see Eq. (22)]. It has an even more complicated behavior with distance r than the sound pressure, having three distinct regions.

An oscillating force applied at a point in space gives rise to results identical to Eq. (21), and hence there are many real sources of sound that behave like the idealized dipole source described above, for example, pure-tone fan noise, vibrating beams, un baffled loudspeakers, and even wires and branches (which sing in the wind due to alternate vortex shedding) (see Chapters 3, 6, 9, and 71).

The next higher order source is the quadrupole. It is thought that the sound produced by the mixing process in an air jet gives rise to stresses that are quadrupole in nature. See Chapters 9, 27, and 28. Quadrupoles may be considered to consist of two opposing point forces (two opposing dipoles) or equivalently four monopoles. (See Table 1.) We note that some authors use slightly different but equivalent definitions for the source strength of monopoles, dipoles, and quadrupoles. The definitions used in Sections 6 and 8 of this chapter are the same as in Crocker and Price⁶ and Fahy⁹ and result in expressions for sound pressure, sound intensity, and sound power, which although equivalent are different in form from those in Chapter 9, for example.

The expression for the sound pressure for a quadrupole is even more complicated than for a dipole. Close to the source, in the near field, the sound pressure $p \propto 1/r^3$. Farther from the sound source, $p \propto 1/r^2$; while in the far field, $p \propto 1/r$.

Sound sources experienced in practice are normally even more complicated than dipoles or quadrupoles. The sound radiation from a vibrating piston is described in Chapter 3. Chapters 9 and 11 in the *Handbook of Acoustics*¹ also describe radiation from dipoles and quadrupoles and the sound radiation from vibrating cylinders in Chapter 9 of the same book.¹

The discussion in Chapter 3 considers steady-state radiation. However, there are many sources in nature and created by people that are transient. As shown in Chapter 9 of the *Handbook of Acoustics*,¹ the harmonic analysis of these cases is often not suitable, and time-domain methods have given better results and understanding of the phenomena. These are the approaches adopted in Chapter 9 of the *Handbook of Acoustics*.¹

7 SOUND INTENSITY

The radial particle velocity in a nondirectional spherically spreading sound field is given by Euler's equation

as

$$u = -\frac{1}{\rho} \int \frac{\partial p}{\partial r} dt \quad (22)$$

and substituting Eqs. (19) and (22) into (10) and then using Eq. (20) and time averaging gives the magnitude of the radial sound intensity in such a field as

$$\langle I \rangle_t = \frac{p_{\text{rms}}^2}{\rho c} \quad (23)$$

the same result as for a plane wave [see Eq. (12)]. The sound intensity decreases with the inverse square of the distance r . Simple omnidirectional monopole sources radiate equally well in all directions. More complicated idealized sources such as dipoles, quadrupoles, and vibrating piston sources create sound fields that are directional. Of course, real sources such as machines produce even more complicated sound fields than these idealized sources. (For a more complete discussion of the sound fields created by idealized sources, see Chapter 3 of this book and Chapters 3 and 8 in the *Handbook of Acoustics*.¹) However, the same result as Eq. (23) is found to be true for any source of sound as long as the measurements are made sufficiently far from the source. The intensity is not given by the simple result of Eq. (23) close to idealized sources such as dipoles, quadrupoles, or more complicated real sources of sound such as vibrating structures. Close to such sources Eq. (10) must be used for the instantaneous radial intensity, and

$$\langle I \rangle_t = \langle pu \rangle_t \quad (24)$$

for the time-averaged radial intensity.

The time-averaged radial sound intensity in the far field of a dipole is given by⁶

$$\langle I \rangle_t = \frac{\rho c k^4 (Ql)^2 \cos^2 \theta}{32\pi^2 r^2}. \quad (25)$$

8 SOUND POWER OF SOURCES

8.1 Sound Power of Idealized Sound Sources

The *sound power* W of a sound source is given by integrating the intensity over any imaginary closed surface S surrounding the source (see Fig. 3):

$$W = \int_S \langle I_n \rangle_t dS \quad (26)$$

The normal component of the intensity I_n must be measured in a direction perpendicular to the elemental area dS . If a spherical surface, whose center coincides with the source, is chosen, then the sound power of an omnidirectional (monopole) source is

$$W_m = \langle I_r \rangle_t 4\pi r^2 \quad (27a)$$

$$W_m = \frac{p_{\text{rms}}^2}{\rho c} 4\pi r^2 \quad (27b)$$

Figure 3 Imaginary surface area S for integration.

and from Eq. (20) the sound power of a monopole is^{6,9}

$$W_m = \frac{\rho c k^2 Q^2}{8\pi} \quad (28)$$

It is apparent from Eq. (28) that the sound power of an idealized (monopole) source is independent of the distance r from the origin, at which the power is calculated. This is the result required by conservation of energy and also to be expected for all sound sources.

Equation (27b) shows that for an omnidirectional source (in the absence of reflections) the sound power can be determined from measurements of the mean-square sound pressure made with a single microphone. Of course, for real sources, in environments where reflections occur, measurements should really be made very-close to the source, where reflections are presumably less important.

The sound power of a dipole source is obtained by integrating the intensity given by Eq. (25) over a sphere around the source. The result for the sound power is

$$W_d = \frac{\rho c k^4 (Ql)^2}{24\pi} \quad (29)$$

The dipole is obviously a much less efficient radiator than a monopole, particularly at low frequency.

In practical situations with real directional sound sources and where background noise and reflections are important, use of Eq. (27b) becomes difficult and less accurate, and then the sound power is more conveniently determined from Eq. (26) with a sound intensity measurement system. See Chapter 45 in this book and Chapter 106 in the *Handbook of Acoustics*.¹

We note that since $p/u_r = \rho c$ (where ρ = mean air density kg/m³ and c = speed of sound 343 m/s) for a plane wave or sufficiently far from any source,

that

$$I_r = \frac{1}{T} \int_0^T \frac{p^2(t)}{\rho c} dt = \frac{p_{\text{rms}}^2}{\rho c} \quad (30)$$

where Eq. (30) is true for random noise for a single frequency sound, known as a pure tone.

Note that for such cases we only need to measure the mean-square sound pressure with a simple sound level meter (or at least a simple measurement system) to obtain the sound intensity from Eq. (30) and then from that the sound power W watts from Eq. (26) is

$$W = \int_S \frac{p_{\text{rms}}^2}{\rho c} dS = 4\pi r^2 \frac{p_{\text{rms}}^2}{\rho c} \quad (31)$$

for an omnidirectional source (monopole) with no reflections and background noise. This result is true for noise signals and pure tones that are produced by omnidirectional sources and in the so-called far acoustic field.

For the special case of a pure-tone (single-frequency) source of sound pressure amplitude, \hat{p} , we note $I_r = \hat{p}^2/2\rho c$ and $W = 2\pi r^2 \hat{p}^2/\rho c$ from Eq. (31).

For measurements on a hemisphere, $W = 2\pi r^2 p_{\text{rms}}^2/\rho c$ and for a pure-tone source $I_r = \hat{p}^2/2\rho c$, and $W = \pi r^2 \hat{p}^2/\rho c$, from Eq. (31).

Note that in the general case, the source is *not* omnidirectional, or more importantly, we must often measure quite close to the source so that we are in the *near* acoustic field, not the *far* acoustic field. However, if appreciable reflections or background noise (i.e., other sound sources) are present, then we *must* measure the intensity I_r in Eq. (26). Figure 4 shows two different enclosing surfaces that can be used to determine the sound power of a source. The sound intensity I_n must always be measured perpendicular (or normal) to the enclosing surfaces used. Measurements are normally made with a two-microphone probe (see Chapter 45). The most common microphone arrangement is the face-to-face model (see Fig. 5).

The microphone arrangement shown also indicates the microphone separation distance, Δr , needed for the intensity calculations. See Chapter 45. In the face-to-face arrangement a solid cylindrical spacer is often put between the two microphones to improve the performance.

Example 1 By making measurements around a source (an engine exhaust pipe) it is found that it is largely omnidirectional at low frequency (in the range of 50 to 200 Hz). If the measured sound pressure level on a spherical surface 10 m from the source is 60 dB at 100 Hz, which is equivalent to a mean-square sound pressure p_{rms}^2 of $(20 \times 10^{-3})^2$ (Pa)², what is the sound power in watts at 100 Hz frequency? Assume $\rho = 1.21$ kg/m³ and $c = 343$ m/s, so $\rho c = 415 \approx 400$ rayls:

$$p_{\text{rms}}^2 = (20 \times 10^{-3})^2 = 400 \times 10^{-6} \text{ (Pa)}^2$$

Figure 4 Sound intensity I_n , being measured on (a) segment dS of an imaginary hemispherical enclosure surface and (b) an elemental area dS of a rectangular enclosure surface surrounding a source having a sound power W .

Figure 5 Sound intensity probe microphone arrangement commonly used.

then from Eq. (31):

$$W = 4\pi r^2 (400 \times 10^{-6}) / \rho c$$

$$W = 4\pi (100 \times 400 \times 10^{-6}) / 400$$

$$\approx 4\pi \times 10^{-4} \approx 1.26 \times 10^{-3} \text{ watts}$$

Example 2 If the sound intensity level, measured using a sound intensity probe at the same frequency, as in Example 1, but at 1 m from the exhaust exit, is 80 dB (which is equivalent to 0.0001 W/m^2), what is the sound power of the exhaust source at this frequency?

From Eq. (26)

$$W = \int_S I_r dS = (0.0001) \times 4\pi(1)^2$$

(for an omnidirectional source). Then

$$W = 1.26 \times 10^{-3} \text{ watts}$$

(the same result as Example 1).

Sound intensity measurements do and should give the same result as sound pressure measurements made in a free field.

Far away from complicated sound sources, provided there is no background noise, and reflections can be ignored:

$$p_{\text{rms}}^2 = \rho c W / (4\pi r^2) \quad (32)$$

$$p_{\text{rms}}^2 / p_{\text{ref}}^2 = (W / W_{\text{ref}})(1/r^2) \rho c W_{\text{ref}} / [p_{\text{ref}}^2 4\pi(1)^2] \quad (33)$$

And by taking 10 log throughout this equation

$$L_p = L_W - 20 \log r - 11 \text{ dB} \quad (34)$$

where L_p = sound pressure level

L_W = source sound power level

r = distance, in metres, from the source center

(Note we have assumed here that $\rho c = 415 \cong 400$ rayls.)

If $\rho c \cong 400$ rayls ($\text{kg/m}^2\text{s}$), then since

$$I = p_{\text{rms}}^2 / \rho c \quad (35)$$

$$I / I_{\text{ref}} = (p_{\text{rms}}^2 / p_{\text{ref}}^2)(p_{\text{ref}}^2 / I_{\text{ref}} \rho c)$$

So,

$$L_I = L_p + 10 \log \left[\frac{400 \times 10^{-12}}{1} \frac{1}{10^{-12} \times 400} \right] \quad (36)$$

$$L_I = L_p + 0 \text{ dB}$$

9 SOUND SOURCES ABOVE A RIGID HARD SURFACE

In practice many real engineering sources (such as machines and vehicles) are mounted or situated on hard reflecting ground and concrete surfaces. If we can assume that the source of power W radiates only to a half-space solid angle 2π , and no power is absorbed by the hard surface (Fig. 6), then

$$I = W / 2\pi r^2$$

$$L_p \cong L_I = L_W - 20 \log r - 8 \text{ dB} \quad (37)$$

Figure 6 Source above a rigid surface.

where L_W is the sound power level of the source and r is the distance in metres.

In this discussion we have assumed that the sound source radiates the same sound intensity in all directions, that is, it is omnidirectional. If the source of sound power W becomes directional, the mean-square sound pressure in Eqs. (32) and (35) will vary with direction, and the sound power W can only be obtained from Eqs. (26) and (31) by measuring either the mean-square pressure (p_{rms}^2) all over a surface enclosing the source (in the far acoustic field, the far field) and integrating Eq. (31) over the surface, or by measuring the intensity all over the surface in the *near* or *far* acoustic field and integrating over the surface [Eq. (26)]. We shall discuss source directivity in Section 10.

Example 3 If the sound power level of a source is 120 dB (which is equivalent to 1 acoustical watt), what is the sound pressure level at 50 m (a) for radiation to whole space and (b) for radiation to half-space?

(a) For whole space:

$$I = 1/4\pi(50)^2 = 1/10^4 \pi (\text{W/m}^2), \text{ then}$$

$$L_I = 10 \log(10^{-4} / \pi 10^{-12})$$

$$(\text{since } I_{\text{ref}} = 10^{-12} \text{ W/m}^2)$$

$$= 10 \log 10^8 - 10 \log \pi$$

$$= 80 - 5 = 75 \text{ dB}$$

Since we may assume $r = 50$ m is in the far acoustic field, $L_p \cong L_I = 75$ dB as well (we have also assumed $\rho c \cong 400$ rayls).

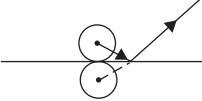

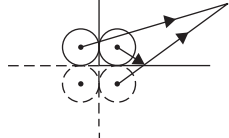

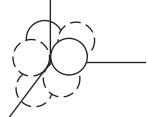

b) For half space:

$$I = 1/2\pi(50)^2 = 2/10^4 \pi (\text{W/m}^2), \text{ then}$$

$$L_I = 10 \log(2 \times 10^{-4} / \pi 10^{-12})$$

$$\text{since } I_{\text{ref}} = 10^{-12} \text{ W/m}^2$$

Table 2 Simple Source Near Reflecting Surfaces^a

Intensity	Source	Condition	Number of Images	p_{rms}^2	Power	D	DI
I		Free field	None	p_{rms}^2	W	1	0 dB
$4I$		Reflecting plane	1	$4p_{rms}^2$	$2W$	4	6 dB
$16I$		Wall-floor intersection	3	$16p_{rms}^2$	$4W$	16	12 dB
$64I$		Room corner	7	$64p_{rms}^2$	$8W$	64	18 dB

^a D and DI are defined in Eqs. (38), (43), and (45).

$$\begin{aligned}
 &= 10 \log 2 + 10 \log 10^8 - 10 \log \pi \\
 &= 80 + 3 - 5 = 78 \text{ dB}
 \end{aligned}$$

and $L_p \cong L_I = 78 \text{ dB}$ also.

It is important to note that the sound power radiated by a source can be significantly affected by its environment. For example, if a simple constant-volume velocity source (whose strength Q will be unaffected by the environment) is placed on a floor, its sound power will be doubled (and its sound power level increased by 3 dB). If it is placed at a floor-wall intersection, its sound power will be increased by four times (6 dB); and if it is placed in a room corner, its power is increased by eight times (9 dB). See Table 2. Many simple sources of sound (ideal sources, monopoles, and real small machine sources) produce more sound power when put near reflecting surfaces, provided their surface velocity remains constant. For example, if a monopole is placed touching a hard plane, an image source of equal strength may be assumed.

10 DIRECTIVITY

The sound intensity radiated by a dipole is seen to depend on $\cos^2\theta$. See Fig. 7.

Most real sources of sound become directional at high frequency, although some are almost omnidirectional at low frequency (depending on the source dimension, d , they must be small in size compared with a wavelength λ , so $d/\lambda \ll 1$ for them to behave almost omnidirectionally).

Directivity Factor [$D(\theta, \phi)$] In general, a directivity factor $D_{\theta, \phi}$ may be defined as the ratio of the radial

Figure 7 Polar directivity plots for the radial sound intensity in the far field of (a) monopole, (b) dipole, and (c) (lateral) quadrupole.

Figure 8 Geometry used in derivation of directivity factor.

intensity $\langle I_{\theta, \phi} \rangle_t$ (at angles θ and ϕ and distance r from the source) to the radial intensity $\langle I_s \rangle_t$ at the same distance r radiated from an omnidirectional source of the same total power (Fig. 8). Thus

$$D_{\theta, \phi} = \frac{\langle I_{\theta, \phi} \rangle_t}{\langle I_s \rangle_t} \quad (38)$$

For a directional source, the mean square sound pressure measured at distance r and angles θ and ϕ is $p_{rms}^2(\theta, \phi)$.

In the far field of this source ($r \gg \lambda$), then

$$W = \int_S \frac{p_{rms}^2(\theta, \phi)}{\rho c} dS \quad (39)$$

But if the source were omnidirectional of the same power W , then

$$W = \int_S \frac{p_{rms}^2}{\rho c} dS \quad (40)$$

where p_{rms}^2 is a constant, independent of angles θ and ϕ

We may therefore write:

$$W = \frac{1}{\rho c} \int_S p_{rms}^2(\theta, \phi) dS = \frac{p_{rms}^2}{\rho c} \int_S dS \quad (41)$$

and

$$p_{rms}^2 = p_s^2 = \frac{1}{S} \int_S p^2(\theta, \phi) dS \quad (42)$$

where p_s^2 is the space-averaged mean-square sound pressure.

We define the directivity factor D as

$$D(\theta, \phi) = \frac{p_{rms}^2(\theta, \phi)}{p_s^2} \text{ or } D(\theta, \phi) = \frac{p_{rms}^2(\theta, \phi)}{p_{rms}^2} \quad (43)$$

as the ratio of the mean-square pressure at distance r to the space-averaged mean-square pressure at r , or the ratio of the mean-square sound pressure at r divided by the mean-square sound pressure at r for an omnidirectional sound source of the same sound power W , watts.

Directivity Index The directivity index DI is just a logarithmic version of the directivity factor. It is expressed in decibels.

A directivity index $DI_{\theta, \phi}$ may be defined, where

$$DI_{\theta, \phi} = 10 \log D_{\theta, \phi} \quad (44)$$

$$DI(\theta, \phi) = 10 \log D(\theta, \phi) \quad (45)$$

Note if the source power remains the same when it is put on a hard rigid infinite surface $D(\theta, \phi) = 2$ and $DI(\theta, \phi) = 3$ dB.

Directivity factor:

$$D = \frac{p_{rms}^2(\theta, \phi)}{p_s^2} \quad (46)$$

Directivity index:

$$DI = 10 \log[D(\theta, \phi)] \quad (47)$$

Numerical Example

1. If a constant-volume velocity source of sound power level of 120 dB (which is equivalent to 1 acoustic watt) radiates to whole space and it has a directivity factor of 12 at 50 m, what is the sound pressure level in that direction?

$$I = 1/4\pi(50)^2 = 1/10^4 \pi (W/m^2)$$

then

$$\langle L_I \rangle_S = 10 \log(10^{-4}/\pi 10^{-12})$$

$$(\text{since } I_{\text{ref}} = 10^{-12} \text{ W/m}^2)$$

$$= 10 \log 10^8 - 10 \log \pi = 75 \text{ dB}$$

But for the directional source $L_p(\theta, \phi) = \langle L_p \rangle_S + DI(\theta, \phi)$, then assuming $\rho c = 400$ rayls,

$$L_p(\theta, \phi) = 75 + 10 \log 12$$

$$= 75 + 10 + 10 \log 1.2 = 85.8 \text{ dB}$$

2. If this constant-volume velocity source is put very near a hard reflecting floor, what will its sound pressure level be in the same direction?

If the direction is away from the floor, then

$$L_p(\theta, \phi) = 85.8 + 6 = 91.8 \text{ dB}$$

11 LINE SOURCES

Sometimes noise sources are distributed more like idealized *line sources*. Examples include the sound radiated from a long pipe containing fluid flow or the sound radiated by a stream of vehicles on a highway. If sound sources are distributed continuously along a straight line and the sources are radiating sound independently, so that the sound power/unit length is W' watts/metre, then assuming cylindrical spreading (and we are located in the far acoustic field again and $\rho c = 400$ rayls):

$$I = W'/2\pi r \quad (48)$$

so,

$$L_I = 10 \log(I/I_{\text{ref}}) = 10 \log(W'/2 \times 10^{-12} \pi r)$$

then

$$L_p \cong L_I = 10 \log(W'/r) + 112 \text{ dB} \quad (49)$$

and for half-space radiation (such as a line source on a hard surface, such as a road)

$$L_p \cong L_I = 10 \log(W'/r) + 115 \text{ dB} \quad (50)$$

12 REFLECTION, REFRACTION, SCATTERING, AND DIFFRACTION

For a homogeneous plane sound wave at normal incidence on a fluid medium of different characteristic impedance ρc , both reflected and transmitted waves are formed (see Fig. 9).

From energy considerations (provided no losses occur at the boundary) the sum of the reflected

intensity I_r and transmitted intensity I_t equals the incident intensity I_i :

$$I_i = I_r + I_t \quad (51)$$

and dividing throughout by I_i ,

$$\frac{I_r}{I_i} + \frac{I_t}{I_i} = R + T = 1 \quad (52)$$

where R is the *energy reflection coefficient* and T is the *transmission coefficient*. For plane waves at normal incidence on a plane boundary between two fluids (see Fig. 9):

$$R = \frac{(\rho_1 c_1 - \rho_2 c_2)^2}{(\rho_1 c_1 + \rho_2 c_2)^2} \quad (53)$$

and

$$T = \frac{4\rho_1 c_1 \rho_2 c_2}{(\rho_1 c_1 + \rho_2 c_2)^2} \quad (54)$$

Some interesting facts can be deduced from Eqs. (53) and (54). Both the reflection and transmission coefficients are independent of the direction of the wave since interchanging $\rho_1 c_1$ and $\rho_2 c_2$ does not affect the values of R and T . For example, for sound waves traveling from air to water or water to air, almost complete reflection occurs, independent of direction, and the reflection coefficients are the same and the transmission coefficients are the same for the two different directions.

As discussed before, when the characteristic impedance ρc of a fluid medium changes, incident sound waves are both reflected and transmitted. It can be shown that if a plane sound wave is incident at an oblique angle on a plane boundary between two fluids, then the wave transmitted into the changed medium changes direction. This effect is called *refraction*. Temperature changes and wind speed changes in the atmosphere are important causes of refraction.

Wind speed normally increases with altitude, and Fig. 10 shows the refraction effects to be expected for an idealized wind speed profile. Atmospheric temperature changes alter the speed of sound c , and temperature gradients can also produce sound shadow and focusing effects, as seen in Figs. 11 and 12.

When a sound wave meets an obstacle, some of the sound wave is deflected. The *scattered* wave is defined to be the difference between the resulting

Figure 9 Incident intensity I_i , reflected intensity I_r , and transmitted intensity I_t in a homogeneous plane sound wave at normal incidence on a plane boundary between two fluid media of different characteristic impedances $\rho_1 c_1$ and $\rho_2 c_2$.

Figure 10 Refraction of sound in air with wind speed $U(h)$ increasing with altitude h .

Figure 11 Refraction of sound in air with normal temperature lapse (temperature decreases with altitude).

Figure 12 Refraction of sound in air with temperature inversion.

wave with the obstacle and the undisturbed wave without the presence of the obstacle. The scattered wave spreads out in all directions interfering with the undisturbed wave. If the obstacle is very small compared with the wavelength, no sharp-edged sound shadow is created behind the obstacle. If the obstacle is large compared with the wavelength, it is normal to say that the sound wave is *reflected* (in front) and *diffracted* (behind) the obstacle (rather than *scattered*). In this case a strong sound shadow is caused in which the wave pressure amplitude is very small. In the zone between the sound shadow and the region fully "illuminated" by the source, the sound wave pressure amplitude oscillates. These oscillations are maximum near the shadow boundary and minimum well inside the shadow. These oscillations in amplitude are normally termed *diffraction bands*. One of the most common examples of diffraction caused by a body is the diffraction of sound over the sharp edge of a

barrier or screen. For a plane homogeneous sound wave it is found that a strong shadow is caused by high-frequency waves where $h/\lambda \geq 1$ and a weak shadow where $h/\lambda \leq 1$, where h is the barrier height and λ is the wavelength. For intermediate cases where $h/\lambda \approx 1$, a variety of interference and diffraction effects are caused by the barrier. Scattering is caused not only by obstacles placed in the wave field but also by fluid regions where the properties of the medium such as its density or compressibility change their values from the rest of the medium. Scattering is also caused by turbulence (see Chapters 5 and 28 in the *Handbook of Acoustics*¹) and from rain or fog particles in the atmosphere and bubbles in water and by rough or absorbent areas on wall surfaces.

13 RAY ACOUSTICS

There are three main modeling approaches in acoustics, which may be termed wave acoustics, ray acoustics, and energy acoustics. So far in this chapter we have mostly used the wave acoustics approach in which the acoustical quantities are completely defined as functions of space and time. This approach is practical in certain cases where the fluid medium is bounded and in cases where the fluid is unbounded as long as the fluid is homogeneous. However, if the fluid properties vary in space due to variations in temperature or due to wind gradients, then the wave approach becomes more difficult and other simplified approaches such as the ray acoustics approach described here and in Chapter 3 of the *Handbook of Acoustics*¹ are useful. This approach can also be extended to propagation in fluid-submerged elastic structures, as described in Chapter 4 of the *Handbook of Acoustics*.¹ The energy approach is described in Section 14.

In the ray acoustics approach, rays are obtained that are solutions to the simplified eikonal equation [Eq. (55)]:

$$\left(\frac{\partial S}{\partial x}\right)^2 + \left(\frac{\partial S}{\partial y}\right)^2 + \left(\frac{\partial S}{\partial z}\right)^2 - \frac{1}{c^2} = 0 \quad (55)$$

The ray solutions can provide good approximations to more exact acoustical solutions. In certain cases they also satisfy the wave equation.⁸ The eikonal $S(x, y, z)$ represents a surface of constant phase (or wavefront) that propagates at the speed of sound c . It can be shown that Eq. (55) is consistent with the wave equation only in the case when the frequency is very high.⁷ However, in practice, it is useful, provided the changes in the speed of sound c are small when measured over distances comparable with the wavelength. In the case where the fluid is homogeneous (constant sound speed c and density ρ throughout), S is a constant and represents a plane surface given by $S = (\alpha x + \beta y + \gamma z)/c$, where α , β , and γ are the direction cosines of a straight line (a ray) that is perpendicular to the wavefront (surface S). If the fluid can no longer be assumed to be homogeneous and the speed of sound $c(x, y, z)$ varies with position, the approach becomes approximate only. In this case some parts

of the wavefront move faster than others, and the rays bend and are no longer straight lines. In cases where the fluid has a mean flow, the rays are no longer quite parallel to the normal to the wavefront. This ray approach is described in more detail in several books and in Chapter 3 of the *Handbook of Acoustics*¹ (where in this chapter the main example is from underwater acoustics). The ray approach is also useful for the study of propagation in the atmosphere and is a method to obtain the results given in Figs. 10 to 12. It is observed in these figures that the rays always bend in a direction toward the region where the sound speed is less. The effects of wind gradients are somewhat different since in that case the refraction of the sound rays depends on the relative directions of the sound rays and the wind in each fluid region.

14 ENERGY ACOUSTICS

In enclosed spaces the wave acoustics approach is useful, particularly if the enclosed volume is small and simple in shape and the boundary conditions are well defined. In the case of rigid walls of simple geometry, the wave equation is used, and after the applicable boundary conditions are applied, the solutions for the natural (eigen) frequencies for the modes (standing waves) are found. See Chapters 4 and 103, and Chapter 6 in the *Handbook of Acoustics*¹ for more details. However, for large rooms with irregular shape and absorbing boundaries, the wave approach becomes impracticable and other approaches must be sought. The ray acoustics approach together with the multiple-image-source concept is useful in some room problems, particularly in auditorium design or in factory spaces where barriers are involved. However, in many cases a statistical approach where the energy in the sound field is considered is the most useful. See Chapters 17 and 104 and also Chapters 60–62 in the *Handbook of Acoustics*¹ for more detailed discussion of this approach. Some of the fundamental concepts are briefly described here.

For a plane wave progressing in one direction in a duct of unit cross section area, all of the sound energy in a column of fluid c metres in length must pass through the cross section in 1 s. Since the intensity $\langle I \rangle_t$ is given by $p_{\text{rms}}^2/\rho c$, then the total sound energy in the fluid column c metres long must also be equal to $\langle I \rangle_t$. The energy per unit volume ϵ (joules per cubic metre) is thus

$$\epsilon = \frac{\langle I \rangle_t}{c} \quad (56)$$

or

$$\epsilon = \frac{p_{\text{rms}}^2}{\rho c^2} \quad (57)$$

The energy density ϵ may be derived by alternative means and is found to be the same as that given in Eq. (56) in most acoustic fields, except very close to sources of sound and in standing-wave fields. In a room with negligibly small absorption in the air or at the boundaries, the sound field created by a

source producing broadband sound will become very reverberant (the sound waves will reach a point with equal probability from any direction). In addition, for such a case the sound energy may be said to be diffuse if the energy density is the same anywhere in the room. For these conditions the time-averaged intensity incident on the walls (or on an imaginary surface from one side) is

$$\langle I \rangle_t = \frac{1}{4} \epsilon c \quad (58)$$

or

$$\langle I \rangle_t = \frac{p_{\text{rms}}^2}{4\rho c} \quad (59)$$

In any real room the walls will absorb some sound energy (and convert it into heat).

The *absorption coefficient* $\alpha(f)$ of the wall material may be defined as the fraction of the incident sound intensity that is absorbed by the wall surface material:

$$\alpha(f) = \frac{\text{sound intensity absorbed}}{\text{sound intensity incident}} \quad (60)$$

The absorption coefficient is a function of frequency and can have a value between 0 and 1. The *noise reduction coefficient* (NRC) is found by averaging the absorption coefficient of the material at the frequencies 250, 500, 1000, and 2000 Hz (and rounding off the result to the nearest multiple of 0.05). See Chapter 57 in this book and Chapter 75 in the *Handbook of Acoustics*¹ for more detailed discussion on the absorption of sound in enclosures.

15 NEAR FIELD, FAR FIELD, DIRECT FIELD, AND REVERBERANT FIELD

Near to a source, we call the sound field, the *near acoustic field*. Far from the source, we call the field the *far acoustic field*. The extent of the near field depends on:

1. The type of source: (monopole, dipole, size of machine, type of machine, etc.)
2. Frequency of the sound.

In the *near field* of a source, the sound pressure and particle velocity tend to be very nearly *out of phase* ($\approx 90^\circ$).

In the *far field*, the sound pressure and particle velocity are very nearly in phase. Note, far from any source, the sound wave fronts flatten out in curvature, and the waves appear to an observer to be like plane waves. In plane progressive waves, the sound pressure and particle velocity are in phase (provided there are no reflected waves). Thus far from a source (or in a plane progressive wave) $p/u = \rho c$. Note ρc is a real number, so the sound pressure p and particle velocity u must be in phase.

Figure 13 shows the example of a finite monopole source with a normal simple harmonic velocity amplitude U . On the surface of the monopole, the

Figure 13 Example of monopole. On the monopole surface, velocity of surface U = particle velocity in the fluid.

surface velocity is equal to the particle velocity. The particle velocity decreases in inverse proportion to the distance from the source center O .

It is common to make the assumption that $kr = 2\pi fr/c = 10$ is the boundary between the near and far fields. Note this is only one criterion and that there is no sharp boundary, but only a gradual transition. First we should also think of the type and the dimensions of the source and assume, say that $r \gg d$, where d is a source dimension. We might say that $r > 10d$ should also be applied as a secondary criterion to determine when we are in the far field.

Reverberation In a confined space we will get reflections, and far from the source the reflections will dominate. We call this reflection-dominated region the *reverberant field*. The region where reflections are unimportant and where a doubling of distance results in a sound pressure drop of 6 dB is called the *free* or *direct* field. See Fig. 14.

Sound Absorption The sound absorption coefficient α of sound-absorbing materials (curtains, drapes, carpets, clothes, fiber glass, acoustical foams, etc.), is defined as

$$\alpha = \frac{\text{sound energy absorbed}}{\text{sound energy incident}}$$

$$\alpha = \frac{\text{sound power absorbed}}{\text{sound power incident}}$$

$$\alpha = \frac{\text{sound intensity absorbed}}{\text{sound intensity incident}} = \frac{I_a}{I_i} \quad (61)$$

Note α also depends on the angle of incidence. The absorption coefficient of materials depends on frequency as well. See Fig. 15.

Thicker materials absorb more sound energy (particularly important at low frequency).

If all sound energy is absorbed, $\alpha = 1$ (none reflected).
If no sound energy is absorbed, $\alpha = 0$:

$$0 \leq \alpha \leq 1$$

If $\alpha = 1$, the sound absorption is perfect (e.g., a window).

Figure 14 Sound pressure level in an interior sound field.

Figure 15 Sound absorption coefficient α of typical absorbing materials as a function of frequency.

Figure 16 Measurement of reverberation time T_R .

The behavior of sound-absorbing materials is described in more detail in Chapter 57.

Reverberation Time In a reverberant space, the reverberation time T_R is normally defined to be the time for the sound pressure level to drop by 60 dB when the sound source is cut off. See Fig. 16. Different reverberation times are desired for different types of spaces. See Fig. 17. The Sabine formula is often used, $T_R = T_{60}$ (for 60 dB):

$$T_{60} = \frac{55.3V}{cS\bar{\alpha}}$$

where V is room volume (m^3), c is the speed of sound (m/s), S is wall area (m^2), and $\bar{\alpha}$ is the angle-averaged wall absorption coefficient, or

$$T_{60} = \frac{55.3V}{c \sum_{i=1}^n S_i \alpha_i} \quad (62)$$

Figure 17 Examples of recommended reverberation times.

where S_i is i th wall area of absorption coefficient α_i .

In practice, when the reverberation time is measured (see Fig. 16), it is normal practice to ignore the first 5-dB drop in sound pressure level and find the time between the 5-dB and 35-dB drops and multiply this time by 2 to obtain the reverberation time T_R .

Example A room has dimensions $5 \times 6 \times 10 \text{ m}^3$. What is the reverberation time T_{60} if the floor ($6 \times 10 \text{ m}$) has absorbing material $\bar{\alpha} = 0.5$ placed on it? We will assume that $\bar{\alpha} = 0$ on the other surfaces (that are made of hard painted concrete.) (See Fig. 18.)

$$T = 55.3V/cS \bar{\alpha} = 55.3(5 \times 6 \times 10)/(343) \\ (6 \times 10)0.5 = 1.6 \text{ s}$$

Noise Reduction Coefficient Sometimes an average absorption coefficient is given for a material to obtain a single number measure for its absorption performance. This average coefficient is normally called its noise reduction coefficient (NRC). It is usually defined to be the average of the values of α at 250, 500, 1000, and 2000 Hz:

$$\text{NRC} = (\alpha_{250} + \alpha_{500} + \alpha_{1000} + \alpha_{2000})/4 \quad (63)$$

Example: If $\alpha_{250} = 0.25$, $\alpha_{500} = 0.45$, $\alpha_{1000} = 0.65$, and $\alpha_{2000} = 0.81$, what is the NRC?

Solution $\text{NRC} = (0.25 + 0.45 + 0.65 + 0.81)/4 = 0.54$.

Notice that the Sabine reverberation time formula $T_{60} = 0.16V/S \bar{\alpha}$ still predict a reverberation time as $\bar{\alpha} \rightarrow 1$, which does not agree with the physical world. Some improved formulas have been devised by Eyring and Millington-Sette that overcome this problem. Sabine's formula is acceptable, provided $\bar{\alpha} \leq 0.5$.

16 ROOM EQUATION

If we have a *diffuse* sound field (the same sound energy at any point in the room) and the field is also *reverberant* (the sound waves may come from any direction, with equal probability), then the sound intensity striking the wall of the room is found by integrating the plane wave intensity over all angles θ , $0 < \theta < 90^\circ$. This involves a weighting of each

Figure 18 Sound source in anechoic room.

wave by $\cos \theta$, and the average intensity for the wall in a reverberant field becomes

$$I_{\text{rev}} = \frac{p_{\text{rms}}^2}{4\rho c} \quad (64)$$

Note the factor 1/4 compared with the plane wave case.

For a point in a room at distance r from a source of power W watts, we will have a direct field contribution $W/4\pi r^2$ from an omnidirectional source to the mean-square pressure and also a reverberant contribution.

We may define the reverberant field as the field created by waves after the first reflection of direct waves from the source. Thus the energy/second absorbed at the first reflection of waves from the source of sound power W is $W\bar{\alpha}$, where $\bar{\alpha}$ is the average absorption coefficient of the walls. The power thus supplied to the reverberant field is $W(1 - \bar{\alpha})$ (after the first reflection). Since the power lost by the W reverberant field must equal the power supplied to it for steady-state conditions, then

$$S \bar{\alpha} \left(\frac{p_{\text{rms}}^2}{4\rho c} \right) = W(1 - \bar{\alpha}) \quad (65)$$

where p_{rms}^2 is the mean-square sound pressure contribution caused by the reverberant field.

There is also the direct field contribution to be accounted for. If the source is a broadband noise source, these two contributions: (1) the direct term $p_{\text{drms}}^2 = \rho c W / 4\pi r^2$ and (2) the reverberant contribution, $p_{\text{revrms}}^2 = 4\rho c W(1 - \bar{\alpha}) / S \bar{\alpha}$. So,

$$p_{\text{tot}}^2 = (\rho c W) \left[\frac{1}{4\pi r^2} + \frac{4(1 - \bar{\alpha})}{S \bar{\alpha}} \right] \quad (66)$$

and after dividing by p_{ref}^2 , and W_{ref} and taking 10 log, we obtain

$$L_p = L_w + 10 \log \left[\frac{1}{4\pi r^2} + \frac{4}{R} \right] + 10 \log \left(\frac{\rho c}{400} \right) \quad (67)$$

where R is the so-called room constant $S \bar{\alpha} / (1 - \bar{\alpha})$.

Critical Distance The critical distance r_c (or sometimes called reverberation radius) is defined as the distance from the sound where the direct field and reverberant field contributions to p_{rms}^2 are equal:

$$\frac{1}{4\pi r^2} = \frac{4}{R} \quad (68)$$

Thus,

$$r_c = \sqrt{\frac{R}{16\pi}} \quad (69)$$

Figure 19 gives a plot of Eq. (67) (the so-called room equation).

Noise Reduction If we are situated in the reverberant field, we may show from Eq. (67) that the noise level reduction, ΔL , achieved by increasing the sound absorption is

$$\Delta L = L_{p1} - L_{p2} = 10 \log(4/R_1) - 10 \log(4/R_2) \quad (70)$$

$$\therefore \Delta L = 10 \log \left(\frac{R_2}{R_1} \right) \approx 10 \log \left(\frac{S_2 \bar{\alpha}_2}{S_1 \bar{\alpha}_1} \right) \quad (71)$$

Then $A = S \bar{\alpha}$ is sometimes known as the absorption area, m^2 (sabins). This may be assumed to be the area of perfect absorbing material, m^2 (like the area of a perfect open window that absorbs 100% of the sound energy falling on it). If we consider the sound field in a room with a uniform energy density ϵ created by a sound source that is suddenly stopped, then the sound pressure level in the room will decrease.

By considering the sound energy radiated into a room by a directional broadband noise source of sound power W , we may sum together the mean squares of the sound pressure contributions caused by the direct and reverberant fields and after taking logarithms obtain the sound pressure level in the room:

$$L_p = L_W + 10 \log \left(\frac{D_{\theta,\phi}}{4\pi r^2} + \frac{4}{R} \right) + 10 \log \left(\frac{\rho c}{400} \right) \quad (72)$$

where $D_{\theta,\phi}$ is the directivity factor of the source (see Section 7) and R is the so-called room constant:

$$R = \frac{S \bar{\alpha}}{1 - \bar{\alpha}} \quad (73)$$

A plot of the sound pressure level against distance from the source is given for various room constants in Fig. 19. It is seen that there are several different

regions. The near and far fields depend on the type of source (see Section 11 and Chapter 3) and the free field and reverberant field. The free field is the region where the direct term $D_{\theta,\phi}/4\pi r^2$ dominates, and the reverberant field is the region where the reverberant term $4/R$ in Eq. (48) dominates. The so-called critical distance $r_c = (D_{\theta,\phi} R / 16\pi)^{1/2}$ occurs where the two terms are equal.

17 SOUND RADIATION FROM IDEALIZED STRUCTURES

The sound radiation from plates and cylinders in bending (flexural) vibration is discussed in Chapter 6 in this book and Chapter 10 in the *Handbook of Acoustics*.¹ There are interesting phenomena observed with free-bending waves. Unlike sound waves, these are dispersive and travel faster at higher frequency. The bending-wave speed is $c_b = (\omega \kappa c_l)^{1/2}$, where κ is the radius of gyration $h/(12)^{1/2}$ for a rectangular cross section, h is the thickness, and c_l is the longitudinal wave speed $\{E/[\rho(1 - \sigma^2)]\}^{1/2}$, where E is Young's modulus of elasticity, ρ is the material density, and σ is Poisson's ratio. When the bending-wave speed equals the speed of sound in air, the frequency is called the critical frequency (see Fig. 20). The critical frequency is

$$f_c = \frac{c^2}{2\pi \kappa c_l} \quad (74)$$

Above this frequency, f_c , the coincidence effect is observed because the bending wavelength λ_b is greater than the wavelength in air λ (Fig. 21), and trace wave matching always occurs for the sound waves in air at some angle of incidence. See Fig. 22. This has important consequences for the sound radiation from structures and also for the sound transmitted through the structures from one air space to the other.

Figure 19 Sound pressure level in a room (relative to sound power level) as a function of distance r from sound source.

Figure 20 Variation of frequency of bending wave speed c_b on a beam or panel and wave speed in air c .

Figure 21 Variation with frequency of bending wavelength λ_b on a beam or panel and wavelength in air λ .

Figure 22 Diagram showing trace wave matching between waves in air of wavelength λ and waves in panel of trace wavelength λ_T .

For free-bending waves on infinite plates above the critical frequency, the plate radiates efficiently, while below this frequency (theoretically) the plate cannot radiate any sound energy at all. (See Chapter 6.) For finite plates, reflection of the bending waves at the edges of the plates causes standing waves that

allow radiation (although inefficient) from the plate corners or edges even below the critical frequency. In the plate center, radiation from adjacent quarter-wave areas cancels. But radiation from the plate corners and edges, which are normally separated sufficiently in acoustic wavelengths, does not cancel. At very low frequency, sound is radiated mostly by corner modes, then up to the critical frequency, mostly by edge modes. Above the critical frequency the radiation is caused by surface modes with which the whole plate radiates efficiently (see Fig. 23). Radiation from bending waves in plates and cylinders is discussed in detail in Chapter 6 and Chapter 10 of the *Handbook of Acoustics*.¹ Figure 24 shows some comparisons between theory and experiment for the level of the radiation efficiencies for the sound radiation for several practical cases of simply supported and clamped panel structures with acoustical and point mechanical excitation.

Sound transmission through structures is discussed in Chapters 56 and 105 of this book and Chapters 66, 76, and 77 of the *Handbook of Acoustics*.¹

Figures 24a and 24b show the logarithmic value of the radiation efficiency $10 \log \sigma$ plotted against frequency for stiffened and unstiffened plates. See Chapter 6 for further discussion on radiation efficiency θ_{rad} , which is also known as radiation ratio.

18 STANDING WAVES

Standing-wave phenomena are observed in many situations in acoustics and the vibration of strings and elastic structures. Thus they are of interest with almost all musical instruments (both wind and stringed) (see Part XIV in the *Encyclopedia of Acoustics*¹³); in architectural spaces such as auditoria and reverberation rooms; in volumes such as automobile and aircraft cabins; and in numerous cases of vibrating structures, from tuning forks, xylophone bars, bells and cymbals to windows, wall panels, and innumerable other engineering systems including aircraft, vehicle, and ship structural members. With each standing wave is associated a mode shape (or shape of vibration) and an eigen (or natural) frequency. Some of these systems can be idealized to simple one-, two-, or three-dimensional systems. For example, with a simple wind instrument such as a flute, Eq. (1) together with the appropriate spatial boundary conditions can be used to predict the predominant frequency of the sound produced. Similarly, the vibration of a string on a violin can be predicted with an equation identical to Eq. (1) but with the variable p replaced by the lateral string displacement. With such a string, solutions can be obtained for the fundamental and higher natural frequencies (overtones) and the associated standing-wave mode shapes (which are normally sine shapes). In such a case for a string with fixed ends, the so-called overtones are just integer multiples (2, 3, 4, 5, ...) of the fundamental frequency.

The standing wave with the flute and string can be considered mathematically to be composed of two waves of equal amplitude traveling in opposite

Figure 23 Wavelength relations and effective radiating areas for corner, edge, and surface modes. The acoustic wavelength is λ ; while λ_{bx} and λ_{by} are the bending wavelengths in the x and y -direction, respectively. (See also the *Handbook of Acoustics*,¹ Chapter 1.)

Figure 24 Comparison of theoretical and measured radiation ratios σ for a mechanically excited, simply supported thin steel plate ($300 \text{ mm} \times 300 \text{ mm} \times 1.22 \text{ mm}$). (—) Theory (simply supported), (---) theory (clamped edges), (...) theory,¹⁴ and (o) measured.¹⁵ (See *Encyclopedia of Vibration*.¹⁶)

directions. Consider the case of a lateral wave on a string under tension. If we create a wave at one end, it will travel forward to the other end. If this end is fixed, it will be reflected. The original (incident) and reflected waves interact (and if the reflection is equal in strength) a perfect standing wave will be created. In Fig. 26 we show three different frequency waves that have interacted to cause standing waves of different frequencies on the string under tension.

A similar situation can be conceived to exist for one-dimensional sound waves in a tube or duct. If the tube has two hard ends, we can create similar

standing one-dimensional sound waves in the tube at different frequencies. In a tube, the regions of high sound pressure normally occur at the hard ends of the tube, as shown in Fig. 27. See Refs. 18–20.

A similar situation occurs for bending waves on bars, but because the equation of motion is different (dispersive), the higher natural frequencies are not related by simple integers. However, for the case of a beam with simply supported ends, the higher natural frequencies are given by $2^2, 3^2, 4^2, 5^2, \dots$, or $4, 9, 16, 25, \dots$, and the mode shapes are sine shapes again.

Figure 26 Waves on a string: (a) Two opposite and equal traveling waves on a string resulting in standing waves, (b) first mode, $n = 1$, (c) second mode, $n = 2$, and (d) third mode, $n = 3$.

Figure 27 Sound waves in a tube. First mode standing wave for sound pressure in a tube.

The standing waves on two-dimensional systems (such as bending vibrations of plates) may be considered mathematically to be composed of four opposite traveling waves. For simply supported rectangular plates the mode shapes are sine shapes in each direction. For three-dimensional systems such as the air volumes of rectangular rooms, the standing waves may be considered to be made up of eight traveling waves. For a hard-walled room, the sound pressure has a cosine mode shape with the maximum pressure at the walls, and the particle velocity has a sine mode shape with zero normal particle velocity at the walls. See Chapter 6 in the *Handbook of Acoustics*¹ for the natural frequencies and mode shapes for a large number of acoustical and structural systems.

For a three-dimensional room, normally we will have standing waves in three directions with sound pressure maxima at the hard walls.

To understand the sound propagation in a room, it is best to use the three-dimensional wave equation in Cartesian coordinates:

$$\nabla^2 p - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (75)$$

or

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (76)$$

This equation can have solutions that are “random” in time or are for the special case of a pure-tone, “simple harmonic” sound.

The simple harmonic solution is of considerable interest to us because we find that in rooms there are solutions only at certain frequencies. It may be of some importance now to mention both the sinusoidal solution and the equivalent solution using complex notation that is very frequently used in acoustics and vibration theory.

For a one-dimensional wave, the simple harmonic solution to the wave equation is

$$p = \hat{p}_1 \cos[k(ct - x)] + \hat{p}_2 \cos[k(ct + x)] \quad (77)$$

where $k = \omega/c = 2\pi f/c$ (the wavenumber).

The first term in Eq. (77) represents a wave of amplitude \hat{p}_1 traveling in the $+x$ direction. The second term in Eq. (77) represents a wave of amplitude \hat{p}_2 traveling in the $-x$ direction.

The equivalent expression to Eq. (77) using complex notation is

$$p = \text{Re}\{\tilde{P}_1 e^{j(\omega t - kx)}\} + \text{Re}\{\tilde{P}_2 e^{j(\omega t + kx)}\} \quad (78)$$

where $j = \sqrt{-1}$, $\text{Re}\{\}$ means real part; and \tilde{P}_1 and \tilde{P}_2 are complex amplitudes of the sound pressure; remember $k = \omega/c$; $kc = 2\pi f$. Both Eqs. (77) and (78) are solutions to Eq. (75).

For the three-dimensional case (x , y , and z propagation), the sinusoidal (pure tone) solution to Eq. (76) is

$$p = \text{Re}\{\tilde{P} \exp(j[\omega t \pm k_x x \pm k_y y \pm k_z z])\} \quad (79)$$

Note that there are 2^3 (eight) possible solutions given by Eq. (79). Substitution of Eq. (79) into Eq. (76) (the three-dimensional wave equation) gives [from any of the eight (2^3) equations]:

$$\omega^2 = c^2(k_x^2 + k_y^2 + k_z^2) \quad (80)$$

from which the wavenumber k is

$$k = \frac{\omega}{c} = \sqrt{(k_x^2 + k_y^2 + k_z^2)} \quad (81)$$

and the so-called direction cosines with the x , y and z directions are $\cos \theta_x = \pm k_x/k$, $\cos \theta_y = \pm k_y/k$, and $\cos \theta_z = \pm k_z/k$ (see Fig. 28).

Equations (80) and (81) apply to the cases where the waves propagate in unbounded space (infinite space) or finite space (e.g., rectangular rooms).

For the case of rectangular rooms with hard walls, we find that the sound (particle) velocity (perpendicular) to each wall must be zero. By using these boundary conditions in each of the eight solutions to Eq. (27a), we find that $\omega^2 = (2\pi f)^2$ and k^2 in Eqs. (80) and (81) are restricted to only certain discrete values:

$$k^2 = \left(\frac{n_x \pi}{A}\right)^2 + \left(\frac{n_y \pi}{B}\right)^2 + \left(\frac{n_z \pi}{C}\right)^2 \quad (82)$$

or

$$\omega^2 = c^2 k^2$$

Then the room natural frequencies are given by

$$f_{n_x n_y n_z} = \frac{c}{2} \sqrt{\left(\frac{n_x}{A}\right)^2 + \left(\frac{n_y}{B}\right)^2 + \left(\frac{n_z}{C}\right)^2} \quad (83)$$

where A , B , C are the room dimensions in the x , y , and z directions, and $n_x = 0, 1, 2, 3, \dots$; $n_y = 0, 1, 2, 3, \dots$ and $n_z = 0, 1, 2, 3, \dots$. Note n_x , n_y , and n_z are the number of half waves in the x , y , and z directions. Note also for the room case, the eight propagating waves add together to give us a standing wave. The wave vectors for the eight waves are shown in Fig. 29.

There are three types of standing waves resulting in three modes of sound wave vibration: axial, tangential, and oblique modes. Axial modes are a result of sound propagation in only one room direction. Tangential modes are caused by sound propagation in two directions in the room and none in the third direction. Oblique modes involve sound propagation in all three directions.

We have assumed there is no absorption of sound by the walls. The standing waves in the room can be excited by noise or pure tones. If they are excited by pure tones produced by a loudspeaker or a machine

Figure 28 Direction cosines and vector k .

Figure 29 Wave vectors for eight propagating waves.

that creates sound waves exactly at the same frequency as the eigenfrequencies (natural frequencies) f_E of the room, the standing waves are very pronounced. Figures 30 and 31 show the distribution of particle velocity and sound pressure for the $n_x = 1$, $n_y = 1$, and $n_z = 1$ mode in a room with hard reflecting walls. See Chapters 4 and 103 for further discussion of standing-wave behavior in rectangular rooms.

19 WAVEGUIDES

Waveguides can occur naturally where sound waves are channeled by reflections at boundaries and by refraction. Even the ocean can sometimes be considered to be an acoustic waveguide that is bounded above by the air-sea interface and below by the ocean bottom (see Chapter 31 in the *Handbook of Acoustics*¹). Similar channeling effects are also sometimes observed in the atmosphere. (See Chapter 5.) Waveguides are also encountered in musical instruments and engineering applications. Wind instruments may be regarded as waveguides. In addition, waveguides comprised

Figure 30 Standing wave for $n_x = 1$, $n_y = 1$, and $n_z = 1$ (particle velocity shown).

Figure 31 Standing wave for $n_x = 1$, $n_y = 1$, and $n_z = 1$ (sound pressure shown).

of pipes, tubes, and ducts are frequently used in engineering systems, for example, exhaust pipes, air-conditioning ducts and the ductwork in turbines and turbofan engines. The sound propagation in such waveguides is similar to the three-dimensional situation discussed in Section 15 but with some differences. Although rectangular ducts are used in air-conditioning systems, circular ducts are also frequently used, and theory for these must be considered as well. In real waveguides, airflow is often present and complications due to a mean fluid flow must be included in the theory.

For low-frequency excitation only plane waves can propagate along the waveguide (in which the sound pressure is uniform across the duct cross section). However, as the frequency is increased, the so-called first cut-on frequency is reached above which there is a standing wave across the duct cross section caused by the first higher mode of propagation.

For excitation just above this cut-on frequency, besides the plane-wave propagation, propagation in higher order modes can also exist. The higher mode propagation in each direction in a rectangular duct can be considered to be composed of four traveling waves with a vector (ray) almost perpendicular to the duct walls and with a phase speed along the duct that is almost infinite. As the frequency is increased, these vectors point increasingly toward the duct axis, and the phase speed along the duct decreases until at very high frequency it is only just above the speed of sound c . However, for this mode, the sound pressure distribution across duct cross section remains unchanged. As the frequency increases above the first cut-on frequency, the cut-on frequency for the second higher order mode is reached and so on. For rectangular ducts, the solution for the sound pressure distribution for the higher duct modes consists of cosine terms with a pressure maximum at the duct walls, while for circular ducts, the solution involves Bessel functions. Chapter 7 in the *Handbook of Acoustics*¹ explains how sound propagates in both rectangular and circular guides and includes discussion on the complications created by a mean flow, dissipation, discontinuities, and terminations. Chapter 161 in the *Encyclopedia of Acoustics*¹³ discusses the propagation of sound in another class of waveguides, that is, acoustical horns.

20 ACOUSTICAL LUMPED ELEMENTS

When the wavelength of sound is large compared to physical dimensions of the acoustical system under consideration, then the lumped-element approach is useful. In this approach it is assumed that the fluid mass, stiffness, and dissipation distributions can be “lumped” together to act at a point, significantly simplifying the analysis of the problem. The most common example of this approach is its use with the well-known Helmholtz resonator in which the mass of air in the neck of the resonator vibrates at its natural frequency against the stiffness of its volume. A similar approach can be used in the design of loudspeaker enclosures and the concentric resonators in automobile mufflers in which the mass of the gas in the resonator louvers (orifices) vibrates against the stiffness of the resonator (which may not necessarily be regarded completely as a lumped element). Dissipation in the resonator louvers may also be taken into account. Chapter 21 in the *Handbook of Acoustics*¹ reviews the lumped-element approach in some detail.

21 NUMERICAL APPROACHES: FINITE ELEMENTS AND BOUNDARY ELEMENTS

In cases where the geometry of the acoustical space is complicated and where the lumped-element approach cannot be used, then it is necessary to use numerical approaches. In the late 1960s, with the advent of powerful computers, the acoustical finite element method (FEM) became feasible. In this approach the fluid volume is divided into a number of small fluid elements (usually rectangular or triangular), and the equations of motion are solved for the elements, ensuring that the sound pressure and volume velocity are continuous at the node points where the elements are joined. The FEM has been widely used to study the acoustical performance of elements in automobile mufflers and cabins.

The boundary element method (BEM) was developed a little later than the FEM. In the BEM approach the elements are described on the boundary surface only, which reduces the computational dimension of the problem by one. This correspondingly produces a smaller system of equations than the FEM. BEM involves the use of a surface mesh rather than a volume mesh. BEM, in general, produces a smaller set of equations that grows more slowly with frequency, and the resulting matrix is full; whereas the FEM matrix is sparse (with elements near and on the diagonal). Thus computations with FEM are generally less time consuming than with BEM. For sound propagation problems involving the radiation of sound to infinity, the BEM is more suitable because the radiation condition at infinity can be easily satisfied with the BEM, unlike with the FEM. However, the FEM is better suited than the BEM for the determination of the natural frequencies and mode shapes of cavities.

Recently, FEM and BEM commercial software has become widely available. The FEM and BEM are described in Chapters 7 and 8 of this book and in Chapters 12 and 13 in the *Handbook of Acoustics*.¹

22 ACOUSTICAL MODELING USING EQUIVALENT CIRCUITS

Electrical analogies have often been found useful in the modeling of acoustic systems. There are two alternatives. The sound pressure can be represented by voltage and the volume velocity by current, or alternatively the sound pressure is replaced by current and the volume velocity by voltage. Use of electrical analogies is discussed in Chapter 11 of the *Handbook of Acoustics*.¹ They have been widely used in loudspeaker design and are in fact perhaps most useful in the understanding and design of transducers such as microphones where acoustic, mechanical, and electrical systems are present together and where an overall equivalent electrical circuit can be formulated (see *Handbook of Acoustics*,¹ Chapters 111, 112, and 113). Beranek makes considerable use of electrical analogies in his books.^{11,12} In Chapter 85 of this book and Chapter 14 in the *Handbook of Acoustics*¹ their use in the design of automobile mufflers is described.

CHAPTER 3

SOUND SOURCES

Philip A. Nelson
Institute of Sound and Vibration Research
University of Southampton
Southampton, United Kingdom

1 INTRODUCTION

This chapter will present an introduction to elementary acoustic sources and the sound fields they radiate. Sources of spherical waves at a single frequency are first described with reference to the concept of a pulsating sphere whose surface vibrations are responsible for producing sound radiation. From this idea follows the notion of the point monopole source. Of course, such idealized sources alone are not a good representation of many practical noise sources, but they provide the basic source models that are essential for the analysis of the more complex acoustic source distributions that are encountered in practical noise control problems. These simple models of spherical wave radiation are also used to discuss the ideas of acoustic power radiation, radiation efficiency, and the effect of interaction between different source elements on the net flow of acoustic energy. Further important elementary source models are introduced, and specific reference is made to the sound fields radiated by point dipole and point quadrupole sources. Many important practical problems in noise control involve the noise generated by unsteady flows and, as will be demonstrated in later chapters, an understanding of these source models is an essential prerequisite to the study of sound generated aerodynamically.

2 THE HOMOGENEOUS WAVE EQUATION

It is important to understand the physical and mathematical basis for describing the radiation of sound, and an introduction to the analysis of sound propagation and radiation is presented here. Similar introductions can also be found in several other textbooks on acoustics such as those authored by Pierce,¹ Morse and Ingard,² Dowling and Ffowcs Williams,³ Nelson and Elliott,⁴ Dowling,⁵ Kinsler et al.,⁶ and Skudrzyk.⁷ Acoustic waves propagating in air generate fluctuations in pressure and density that are generally much smaller than the average pressure and density in a stationary atmosphere. Even some of the loudest sounds generated (e.g., close to a jet engine) produce pressure fluctuations that are of the order of 100 Pa, while in everyday life, acoustic pressure fluctuations vary in their magnitude from about 10^{-5} Pa (about the smallest sound that can be detected) to around 1 Pa (typical of the pressure fluctuations generated in a noisy workshop). These fluctuations are much smaller than the typical average atmospheric pressure of about 10^5 Pa. Similarly, the density fluctuations associated with the propagation of some of the loudest sounds generated

are still about a thousand times less than the average density of atmospheric air (which is about 1.2 kg m^{-3}). Furthermore, the pressure fluctuations associated with the propagation of sound occur very quickly, the range of frequencies of sounds that can be heard being typically between 20 Hz and 20 kHz (i.e., the pressure fluctuations occur on a time scale of between 1/20th of a second and 1/20,000th of a second). These acoustic pressure fluctuations can be considered to occur *adiabatically* since the rapid rate of change with time of the pressure fluctuations in a sound wave, and the relatively large distances between regions of increased and decreased pressure, are such that there is a negligible flow of heat from a region of compression to a region of rarefaction. Under these circumstances, it can be assumed that the density change is related only to the pressure change and not to the (small) increase or decrease in temperature in regions of compression or rarefaction. Furthermore, since these pressure and density fluctuations are very small compared to the average values of pressure and density, it can also be assumed that the fluctuations are *linearly* related. It turns out (see, e.g., Pierce,¹ pp. 11–17) that the acoustic pressure fluctuation p is related to the acoustic density fluctuation ρ by $p = c_0^2 \rho$ where c_0 is the speed of sound in air.

The sound speed c_0 in air at a temperature of 20°C and at standard atmospheric pressure is about 343 m s^{-1} and thus it takes an acoustic disturbance in air about one third of a second to propagate 100 m. As sound propagates it also imparts a very small motion to the medium such that the pressure fluctuations are accompanied locally by a fluctuating displacement of the air. This small air movement can be characterized by the local *particle velocity*, a “particle” being thought of as a small volume of air that contains many millions of gas molecules. The typical values of particle velocity associated with the propagation of even very loud sounds are usually less than about 1 m s^{-1} and so the local velocity of the air produced by the passage of a sound wave is actually very much smaller than the speed with which the sound propagates.

Since the acoustic pressure, density, and particle velocity fluctuations associated with sound waves in air are usually relatively small, the equations governing mass and momentum conservation in a fluid continuum can be considerably simplified in order to relate these acoustical variables to one another. The general conservation equations can be *linearized* and terms that are proportional to the product of the acoustical variables can be discarded from the equations. The

equation of mass conservation in a homogeneous three-dimensional medium at rest reduces to

$$\frac{\partial \rho}{\partial t} + \rho_0 \left(\frac{\partial u_1}{\partial x_1} + \frac{\partial u_2}{\partial x_2} + \frac{\partial u_3}{\partial x_3} \right) = 0 \quad (1)$$

where u_1 , u_2 , and u_3 are the three components of the acoustic particle velocity in the x_1 , x_2 , and x_3 directions and ρ_0 is the average density of the medium. This equation can be written more compactly in vector notation such that

$$\frac{\partial \rho}{\partial t} + \rho_0 \nabla \cdot \mathbf{u} = 0 \quad (2)$$

where $\nabla \cdot \mathbf{u}$ is the divergence of the vector \mathbf{u} given by the scalar product of the del operator $\mathbf{i}(\partial/\partial x_1) + \mathbf{j}(\partial/\partial x_2) + \mathbf{k}(\partial/\partial x_3)$ with the velocity vector $\mathbf{i}u_1 + \mathbf{j}u_2 + \mathbf{k}u_3$ where \mathbf{i} , \mathbf{j} , and \mathbf{k} are, respectively, the unit vectors in the x_1 , x_2 , and x_3 directions. Similarly, for an inviscid medium, the linearized equations of momentum conservation in these three coordinate directions reduce to

$$\begin{aligned} \rho_0 \frac{\partial u_1}{\partial t} + \frac{\partial p}{\partial x_1} &= 0 & \rho_0 \frac{\partial u_2}{\partial t} + \frac{\partial p}{\partial x_2} &= 0 \\ \rho_0 \frac{\partial u_3}{\partial t} + \frac{\partial p}{\partial x_3} &= 0 \end{aligned} \quad (3)$$

which can be written more compactly as

$$\rho_0 \frac{\partial \mathbf{u}}{\partial t} + \nabla p = 0 \quad (4)$$

where \mathbf{u} and ∇p are, respectively, the vectors having components (u_1, u_2, u_3) and $(\partial p/\partial x_1, \partial p/\partial x_2, \partial p/\partial x_3)$. Taking the difference between the divergence of Eq. (4) and the time derivative of Eq. (2) and using the relation $p = c_0^2 \rho$ leads to the wave equation for the acoustic pressure fluctuation given by

$$\nabla^2 p - \frac{1}{c_0^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (5)$$

where in rectangular Cartesian coordinates $\nabla^2 p = \partial^2 p/\partial x_1^2 + \partial^2 p/\partial x_2^2 + \partial^2 p/\partial x_3^2$. This equation governs the behavior of acoustic pressure fluctuations in three dimensions. The equation states that the acoustic pressure at any given point in space must behave in such a way to ensure that the second derivative of the pressure fluctuation with respect to time is related to the second derivatives of the pressure fluctuation with respect to the three spatial coordinates. Since the equation follows from the mass and momentum conservation equations, pressure fluctuations satisfying this equation also satisfy these fundamental conservation laws. It is only through finding pressure fluctuations that satisfy this equation that the physical implications of the wave equation become clear.

3 SOLUTIONS OF THE HOMOGENEOUS WAVE EQUATION

The simplest and most informative solutions of the wave equation in three dimensions are those associated with spherically symmetric wave propagation. If it can be assumed that the pressure fluctuations depend only on the radial coordinate r of a system of spherical coordinates, the wave equation reduces to (see Pierce,¹ p. 43)

$$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial p}{\partial r} \right) - \frac{1}{c_0^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (6)$$

and this equation can, after some algebra, be written in the form

$$\frac{\partial^2(r p)}{\partial r^2} - \frac{1}{c_0^2} \frac{\partial^2(r p)}{\partial t^2} = 0 \quad (7)$$

It is easy to show that this equation has solutions given by $r p = f(t - r/c_0)$ or by $r p = g(t + r/c_0)$ where $f(\)$ or $g(\)$ means "a function of." Proof that these functions, of either $t - r/c_0$ or of $t + r/c_0$, are solutions of Eq. (7) can be established by differentiating the functions twice with respect to both r and t and then demonstrating that the resulting derivatives satisfy the equation. It follows, therefore, that the solution for the radially dependent pressure fluctuation is given by

$$p(r, t) = \frac{f(t - r/c_0)}{r} + \frac{g(t + r/c_0)}{r} \quad (8)$$

The function of $t - r/c_0$ describes waves that propagate outward from the origin of the coordinate system, and Fig. 1a illustrates the process of the outward propagation of a particular sound pulse. The figure shows a series of "snapshots" of the acoustic pressure pulse whose time history takes the form

$$f(t) = e^{-\pi(at)^2} \cos \omega_0 t \quad (9)$$

The figure shows that as the radial distance r from the origin is increased, the pressure pulse arrives at a later time; this relative time delay is described by the term $t - r/c_0$.

Also, as the wave propagates outward, the amplitude of the pulse diminishes as the waves spread spherically; this reduction in amplitude with increasing radial distance from the origin is described by the term $1/r$. Figure 1b also shows a series of snapshots of the acoustic pressure associated with waves propagating *inward* toward the origin, and this process is described by the function of $t + r/c_0$. In this case as the radial distance from the origin reduces, then the sound pulse associated with this inward traveling wave will arrive at a progressively later time, the pulses arriving at a radial distance r at a time r/c_0 before the time t at which the pulse arrives at the origin. Obviously the

Figure 1 Series of “snapshots” of the sound field associated with (a) outgoing and (b) incoming spherical acoustic waves.

pressure fluctuations also become greater in amplitude as they converge on the origin, this being again described by the term $1/r$. Inward propagating waves are legitimate solutions of the wave equation under certain circumstances (e.g., inside a spherical vessel; see Skudrzyk,⁷ p. 354, for a discussion). However, it can be argued formally that the solution for inward coming waves is not tenable if one considers sound propagation in a free field since such waves would have to be generated at infinity at an infinite time in the past. The formal mathematical test for the validity of solutions of the wave equation is provided by the Sommerfeld radiation condition (see, e.g. Pierce,² p. 177).

4 SIMPLE HARMONIC SPHERICAL WAVES

It is extremely useful in analyzing acoustical problems to be able to work at a single frequency and make use of complex exponential representations of acoustic wave propagation. For example, we may assume that the acoustic pressure everywhere has a dependence on time of the form $e^{-j\omega t}$ where ω is the angular frequency and j is the square root of -1 . In such a case, the solution for the acoustic pressure as a function of time in the case of spherically symmetric radially

outward propagation can be written as

$$p(r, t) = \text{Re} \left\{ \frac{Ae^{j(\omega t - kr)}}{r} \right\} \quad (10)$$

where Re denotes the “real part of” the complex number in curly brackets and $k = \omega/c_0$ is the wavenumber. The term A is a complex number that describes the amplitude of the wave and its relative phase. Thus, for example, $A = |A|e^{j\phi_A}$ where $|A|$ is the modulus of the complex number and ϕ_A is the phase. The term e^{-jkr} also describes the change in phase of the pressure fluctuation with increasing radial distance from the origin, this phase change resulting directly from the propagation delay r/c_0 . Taking the real part of the complex number in Eq. (10) shows that

$$p(r, t) = \frac{|A| \cos(\omega t - kr + \phi_A)}{r} \quad (11)$$

and this describes the radial dependence of the amplitude and phase of the single frequency pressure fluctuation associated with harmonic outgoing spherical

waves. It is also useful to be able to define a single complex number that represents the amplitude and phase of a single frequency pressure fluctuation, and in this case the complex pressure can be written as

$$p(r) = \frac{Ae^{-jkr}}{r} \quad (12)$$

where the real pressure fluctuation can be recovered from $p(r, t) = \text{Re}\{p(r)e^{j\omega t}\}$. It turns out that in general it is useful to describe the complex acoustic pressure $p(\mathbf{x})$ as a complex number that depends on the spatial position (described here by the position vector \mathbf{x}). This complex pressure must satisfy the single frequency version of the wave equation, or Helmholtz equation, that is given by

$$(\nabla^2 + k^2)p(\mathbf{x}) = 0 \quad (13)$$

It is very straightforward to verify that the complex pressure variation described by Eq. (12) satisfies Eq. (13). It is also useful to describe the other acoustic fluctuations such as density and particle velocity in terms of spatially dependent complex numbers. In the case of spherically symmetric wave propagation, the acoustic particle velocity has only a radial component, and if this is described by the radially dependent complex number $u_r(r)$, it follows that momentum conservation relationship given by Eq. (4) reduces to

$$j\omega\rho_0 u_r(r) + \frac{\partial p(r)}{\partial r} = 0 \quad (14)$$

Assuming the radial dependence of the complex pressure described by Eq. (12) then shows that the complex radial particle velocity can be written as

$$u_r(r) = \frac{A}{j\omega\rho_0} \left(\frac{jk}{r} + \frac{1}{r^2} \right) e^{-jkr} \quad (15)$$

The complex number that describes the ratio of the complex pressure to the complex particle velocity is known as the *specific acoustic impedance*, and this is given by

$$z(r) = \frac{p(r)}{u_r(r)} = \rho_0 c_0 \left(\frac{jkr}{1 + jkr} \right) \quad (16)$$

The modulus of the impedance thus describes the ratio of the amplitudes of the pressure and velocity fluctuations while the phase of the impedance describes the phase difference between the pressure and particle velocity fluctuations. First note that when kr becomes very much greater than unity, then the impedance $z(r) \approx \rho_0 c_0$, where $\rho_0 c_0$ is known as the *characteristic acoustic impedance* of the medium. Since $kr = 2\pi/\lambda$, where λ is the acoustic wavelength, this condition occurs when the distance r is many wavelengths from the origin (where the source of the waves is assumed

to be located). Therefore, many wavelengths from the source, the pressure and velocity fluctuations are in phase with one another, and their amplitudes are related simply by $\rho_0 c_0$. This region is known as the *far field* of the source of the waves. However, when kr is very much smaller than unity, then the impedance $z(r) \approx \rho_0 c_0(jkr)$. This shows that, at distances from the source that are small compared to the wavelength, the particle velocity fluctuation becomes much larger relative to the pressure fluctuation than is the case at many wavelengths from the source. At these small distances, the pressure and particle velocity fluctuations are close to being 90° out of phase. This region is known as the *near field* of the source of the waves.

5 SOURCES OF SPHERICALLY SYMMETRIC RADIATION

A rigid sphere whose surface vibrates to and fro in the radial direction provides a simple conceptual model for the generation of spherical acoustic waves. Such a pulsating sphere can be assumed to have a mean radius a and to produce surface vibrations at a single frequency that are uniform over the surface of the sphere. If these radial vibrations are assumed to have a complex velocity U_a say, then the acoustic pressure fluctuations that result can be found by equating this velocity to the particle velocity of the outward going spherical waves generated. Since the pressure and particle velocity of the waves generated are related by the expression for the impedance given above, it follows that at the radial distance a from the origin upon which the sphere is centered, the complex acoustic pressure is given by

$$p(a) = \frac{Ae^{-jka}}{a} = \rho_0 c_0 \left(\frac{jka}{1 + jka} \right) U_a \quad (17)$$

This equation enables the complex amplitude A of the acoustic pressure to be expressed in terms of the radial surface velocity U_a of the pulsating sphere. It then follows that the radial dependence of the complex acoustic pressure can be written as

$$p(r) = \rho_0 c_0 a \left[\frac{jka}{1 + jka} \right] \frac{U_a e^{-jk(r-a)}}{r} \quad (18)$$

The product of the radial surface velocity U_a and the total surface area of the sphere $4\pi a^2$ provides a measure of the *strength* of such an acoustic source. This product, usually denoted by $q = 4\pi a^2 U_a$, has the dimensions of *volume velocity*, and the pressure field can be written in terms of this source strength as

$$p(r) = \rho_0 c_0 \left[\frac{jk}{1 + jka} \right] \frac{q e^{-jk(r-a)}}{4\pi r} \quad (19)$$

The definition of the sound field generated by a *point monopole source* follows from this equation by

assuming that the radius a of the sphere becomes infinitesimally small but that the surface velocity of the sphere increases to ensure that the product of surface area and velocity (and thus source strength) remains constant. Therefore, as ka tends to zero, the expression for the pressure field becomes

$$p(r) = \rho_0 c_0 j k \frac{q e^{-jkr}}{4\pi r} \quad (20)$$

It is worth noting that this expression can be written in terms of the time derivative of the source strength defined by $\dot{q} = j\omega q$ such that $p(r) = \rho_0 \dot{q} e^{-jkr} / 4\pi r$, and since the term $e^{-jkr} = e^{-j\omega r/c_0}$ represents a pure delay of r/c_0 in the time domain, then the expression for the acoustic pressure as a function of time can be written as

$$p(r, t) = \frac{\rho_0 \dot{q}(t - r/c_0)}{4\pi r} \quad (21)$$

This demonstrates that the acoustic pressure time history replicates exactly the time history of the *volume acceleration* of the source but, of course, delayed by the time that it takes for the sound to travel radially outward by a distance r .

6 ACOUSTIC POWER OUTPUT AND RADIATION EFFICIENCY

The *instantaneous acoustic intensity* defines the local instantaneous rate at which acoustic energy flows per unit surface area in a sound field. It is equal to the product of the local acoustic pressure and the local acoustic particle velocity. The time-averaged acoustic intensity is defined by the vector quantity

$$\mathbf{I}(\mathbf{x}) = \frac{1}{T} \int_{-T/2}^{T/2} p(\mathbf{x}, t) \mathbf{u}(\mathbf{x}, t) dt \quad (22)$$

where T denotes a suitably long averaging time in the case of stationary random fluctuations, or the duration of a period of a single frequency fluctuation. For single frequency fluctuations, this time integral can be written in terms of the complex pressure and particle velocity such that $\mathbf{I}(\mathbf{x}) = (\frac{1}{2}) \text{Re}\{p(\mathbf{x})^* \mathbf{u}(\mathbf{x})\}$ where the asterisk denotes the complex conjugate. The acoustic power output of a source of sound is evaluated by integrating the sound intensity over a surface surrounding the source. Thus, in general

$$W = \int_S \mathbf{I}(\mathbf{x}) \cdot \mathbf{n} dS \quad (23)$$

where \mathbf{n} is the unit vector that is normal to and points outward from the surface S surrounding the source. In the particular case of the pulsating sphere of radius a where the pressure and particle velocity are uniform across the surface of the sphere, the acoustic power output is given by evaluating this

integral over the surface of the sphere. Thus, in this case

$$\begin{aligned} W &= 4\pi a^2 \frac{1}{2} \text{Re}\{p(a)^* U_a\} \\ &= 2\pi a^2 \rho_0 c_0 |U_a|^2 \frac{(ka)^2}{1 + (ka)^2} \end{aligned} \quad (24)$$

This calculation is of considerable assistance in explaining some basic features of the efficiency with which acoustic sources radiate sound. First, note that if the product $ka = 2\pi a/\lambda$ is very large (i.e., the radius of the sphere is very large compared to the acoustic wavelength), then the sound power radiated is given by $W \approx 2\pi a^2 \rho_0 c_0 |U_a|^2$, while if the reverse is true, and ka is very small (i.e., the radius of the sphere is very small compared to the acoustic wavelength), the sound power radiated is approximated by the expression $W \approx 2\pi a^2 \rho_0 c_0 |U_a|^2 (ka)^2$. It is clear that, in the second case, since by definition ka is small, the efficiency with which surface velocity fluctuations are converted into sound power radiated is very much less than in the first case, where the radius of the sphere is very much greater than the acoustic wavelength. It turns out that this is a general characteristic of acoustic sources and more complex radiators of sound are often characterized by their *radiation efficiency* that is defined by the ratio

$$\sigma = \frac{W}{\rho_0 c_0 S (1/2) \langle |U|^2 \rangle} \quad (25)$$

where $\langle |U|^2 \rangle$ denotes the squared modulus of the velocity fluctuation averaged over the surface area S of the body that radiates the acoustic power W . Most sources of sound follow the general trend of relatively inefficient radiation at low frequencies (where the wavelength is much greater than the dimensions of the radiator) and relatively efficient radiation ($\sigma \approx 1$) at high frequencies (where the wavelength becomes smaller than the dimensions of the radiator). Obviously, the exact nature of the surface velocity distribution dictates the radiated sound field and of paramount importance is the interference produced in the sound field between neighboring elements of the effective distribution of source strength.

7 INTERFERENCE BETWEEN POINT SOURCES

The linearity of the wave equation leads to the *principle of superposition*, which in turn implies that the sound field generated by a number of acoustic sources is simply the sum at any instant of the sound fields generated by all of the sources individually (i.e., the sound fields generated by each of the sources when the strengths of all the others is set to zero). For single frequency sound fields, the total complex acoustic pressure is simply found by adding the complex pressures generated by each of the sources. Thus, for

example, if there are N point sources each of strength q_n , then the total complex pressure produced by these sources is given by

$$p(\mathbf{x}) = \frac{\rho_0 c_0 j k q_1 e^{-jkr_1}}{4\pi r_1} + \frac{\rho_0 c_0 j k q_2 e^{-jkr_2}}{4\pi r_2} + \dots + \frac{\rho_0 c_0 j k q_N e^{-jkr_N}}{4\pi r_N} \quad (26)$$

where the distances $r_n = |\mathbf{x} - \mathbf{y}_n|$ are the radial distances to the vector position \mathbf{x} from the vector positions \mathbf{y}_n at which the sources are located. The net sound fields produced by the interference of these individual fields can be highly complex and depend on the geometric arrangement of the sources, their relative amplitudes and phases, and, of course, the angular frequency ω . It is worth illustrating this complexity with some simple examples. Figure 2 shows the interference patterns generated by combinations of two, three, and four monopole sources each separated by one acoustic wavelength when all the source strengths are in phase. Regions of *constructive interference* are shown (light shading) where the superposition of the fields gives rise to an increase in the acoustic pressure

Figure 2 Single frequency sound field generated by (a) two, (b) three, and (c) four point monopole sources whose source strengths are in phase and are separated by a wavelength λ .

amplitude, as are regions of *destructive interference* (dark shading) where the acoustic pressure amplitude is reduced.

It is also worth emphasizing that the energy flow in such sound fields can also be highly complex. It is perfectly possible for energy to flow out of one of the point sources and into another. Figure 3 shows the time-averaged intensity vectors when a source of strength $q_2 = q_1 e^{j\phi}$ is placed at a distance $d = \lambda/16$ apart from a source of strength q_1 when the phase difference $\phi = 4.8kd$. The source of strength q_1 appears to absorb significant power while the source of strength q_2 radiates net power. The power that finds its way into the far field turns out to be a relatively small fraction of the power being exchanged between the sources. The possibility of acoustic sources being net absorbers of acoustic energy may at first sight be unreasonable. However, if one thinks of the source as a pulsating sphere, or indeed the cone of a baffled loudspeaker, whose velocity is prescribed, then it becomes apparent that the source may become a net absorber of energy from the sound field when the net acoustic pressure on the source is close to being out of phase with the velocity fluctuations of the surface. It turns out that the net acoustic power output of a point source can be written as $W = (\frac{1}{2}) \text{Re}\{p^* q\}$, and, if the phase difference between the pressure and volume velocity is given by ϕ_{pq} , then we can write $W = (\frac{1}{2}) |p| |q| \cos \phi_{pq}$. It therefore follows that, if the phase difference ϕ_{pq} is, for example, 180° , then the power W will be negative. Of course, a source radiating alone produces a pressure fluctuation upon its own surface, some of which will be in phase with the velocity of the surface and thereby radiate sound power. As shown by this example, however, if another source produces a net fluctuating pressure on the surface of the source that is out of phase with the velocity of the source, the source can become a net absorber of acoustic energy. The consequences of this for the energy used to drive the fluctuating velocity of

Figure 3 Time-averaged intensity vectors generated by the superposition of the sound fields generated by two point monopole sources q_1 (on the left) and q_2 (on the right) where $q_2 = q_1 e^{j\phi}$, $|q_2| = |q_1|$, $d = \lambda/16$, and $\phi = 108^\circ = 4.8kd$ rad. The dimension of one side of (a) is $\lambda/2$ and one side of (b) is $\lambda/10$, which corresponds to the square depicted in (a).

the source surface can be understood by examination of the detailed electrodynamics of, for example, a moving coil loudspeaker (see Nelson and Elliott,⁴ p. 140). It is concluded that, in practice, the power radiated as sound is generally a small fraction of that necessary to overcome the mechanical and electrical energy losses sustained in producing the requisite surface velocity of the source. Thus, when a loudspeaker acts as an absorber of acoustic energy, there will be a relatively small reduction (of typically a few percent) in the electrical energy consumed in order to produce the necessary vibrations of the loudspeaker cone.

8 THE POINT DIPOLE SOURCE

The sound field radiated by a point dipole source can be thought of as the field radiated by two point monopole sources of the same strength but of opposite phase that are placed very close together compared to the wavelength of the sound radiated. In fact, the point dipole field is exactly equivalent to the field of the two monopoles when they are brought infinitesimally close together in such a way as to keep constant the product of their source strength and their distance apart. Assume that, as illustrated in Fig. 4, one of the monopoles, of strength q say, is located at a vector position $\mathbf{y} + \boldsymbol{\epsilon}$ while the other, of strength $-q$, is located at $\mathbf{y} - \boldsymbol{\epsilon}$. The sound field at the position \mathbf{x} can then be written as

$$p(\mathbf{x}) = \frac{\rho_0 c_0 j k q e^{-j k r_1}}{4 \pi r_1} - \frac{\rho_0 c_0 j k q e^{-j k r_2}}{4 \pi r_2} \quad (27)$$

where the distances from the sources to the field point are, respectively, given by $r_1 = |\mathbf{x} - (\mathbf{y} + \boldsymbol{\epsilon})|$ and $r_2 = |\mathbf{x} - (\mathbf{y} - \boldsymbol{\epsilon})|$. On the assumption that the vector $\boldsymbol{\epsilon}$ is small, one may regard the first term on the right side of Eq. (27) as a function of the vector $\mathbf{y} + \boldsymbol{\epsilon}$ and make use of the Taylor series expansion:

$$f(\mathbf{y} + \boldsymbol{\epsilon}) = f(\mathbf{y}) + \boldsymbol{\epsilon} \cdot \nabla_{\mathbf{y}} f(\mathbf{y}) + \frac{1}{2} (\boldsymbol{\epsilon} \cdot \nabla_{\mathbf{y}})^2 f(\mathbf{y}) + \dots \quad (28)$$

where, for example, $\nabla_{\mathbf{y}} f = \partial f / \partial y_1 \mathbf{i} + \partial f / \partial y_2 \mathbf{j} + \partial f / \partial y_3 \mathbf{k}$ such that $\nabla_{\mathbf{y}}$ is the del operator in the y coordinates. Similarly, the second term on the right

Figure 4 Coordinate system for the analysis of the dipole source.

side of Eq. (27) can be regarded as a function $f(\mathbf{y} - \boldsymbol{\epsilon})$, and, therefore, in the limit that $\boldsymbol{\epsilon} \rightarrow 0$, it is possible to make the following approximations:

$$\frac{e^{-j k r_1}}{4 \pi r_1} \approx \frac{e^{-j k r}}{4 \pi r} + \boldsymbol{\epsilon} \cdot \nabla_{\mathbf{y}} \left(\frac{e^{-j k r}}{4 \pi r} \right) \quad (29a)$$

$$\frac{e^{-j k r_2}}{4 \pi r_2} \approx \frac{e^{-j k r}}{4 \pi r} - \boldsymbol{\epsilon} \cdot \nabla_{\mathbf{y}} \left(\frac{e^{-j k r}}{4 \pi r} \right) \quad (29b)$$

where $r = |\mathbf{x} - \mathbf{y}|$ and the higher order terms in the Taylor series are neglected. Substitution of these approximations into Eq. (27) then shows that

$$p(\mathbf{x}) = \rho_0 c_0 j k (q \mathbf{d}) \cdot \nabla_{\mathbf{y}} \left(\frac{e^{-j k r}}{4 \pi r} \right) \quad (30)$$

where the vector $\mathbf{d} = 2\boldsymbol{\epsilon}$ and the product $(q \mathbf{d})$ is the *vector dipole strength*. It is this product that is held constant as the two monopoles are brought infinitesimally close together. Noting that

$$\begin{aligned} \nabla_{\mathbf{y}} \left(\frac{e^{-j k r}}{4 \pi r} \right) &= (\nabla_{\mathbf{y}} r) \frac{\partial}{\partial r} \left(\frac{e^{-j k r}}{4 \pi r} \right) \\ &= -\frac{(\mathbf{x} - \mathbf{y})}{r} \frac{\partial}{\partial r} \left(\frac{e^{-j k r}}{4 \pi r} \right) \end{aligned} \quad (31)$$

and since $(\mathbf{x} - \mathbf{y})/r = \mathbf{n}_r$ is the unit vector pointing from the source to the field point, the expression for the dipole field reduces to

$$p(\mathbf{x}) = -\rho_0 c_0 k^2 (q \mathbf{d}) \cdot \mathbf{n}_r \left(\frac{e^{-j k r}}{4 \pi r} \right) \left(1 + \frac{1}{j k r} \right) \quad (32)$$

If θ defines the angle between the vector \mathbf{n}_r and the axis of the dipole (defined by the direction of the vector \mathbf{d}), then $\mathbf{d} \cdot \mathbf{n}_r = d \cos \theta$, and the strong directivity of the dipole source becomes apparent. It is also evident that when kr is small (i.e., the field point is a relatively small number of wavelengths from the source), then the “near-field” term given by $1/jkr$ has an influence on the pressure fluctuations produced, but that this term vanishes in the far field (as $kr \rightarrow \infty$). It can also be shown that this sound field is identical to that produced by a fluctuating point force \mathbf{f} applied to the medium where the force is given by $\mathbf{f} = \rho_0 c_0 j k q \mathbf{d}$. A simple practical example of a dipole source is that of an open-backed loudspeaker radiating sound whose wavelength is much greater than the loudspeaker dimensions. Such a source applies a fluctuating force to the surrounding medium without introducing any net fluctuating volume flow into the surrounding medium. The dipole source also has considerable utility in modeling the process of aerodynamic sound generation; it turns out that the sound generated by turbulence interacting with a rigid body at low Mach numbers can be modeled as if

the sound were generated by a distribution of dipole sources on the surface of the body. The strengths of these dipoles are given exactly by the fluctuations in force applied locally by the unsteady flow to the body.

9 POINT QUADRUPOLE SOURCES

The approach taken to deriving the field of the point dipole source can also be more generally applied to other arrangements of point monopole sources. Thus, for example, if there are N point monopoles of strength q_n clustered around a point defined by the position vector \mathbf{y} such that the n th source has a position vector $\mathbf{y} + \mathbf{e}_n$, the total field at \mathbf{x} can be written as

$$p(\mathbf{x}) = \sum_{n=1}^N \frac{\rho_0 c_0 j k q_n e^{-jkr_n}}{4\pi r_n} \quad (33)$$

where $r_n = |\mathbf{x} - (\mathbf{y} + \mathbf{e}_n)|$. Each of the terms in this summation can then be expanded as a Taylor series such that

$$\begin{aligned} \frac{e^{-jkr_n}}{4\pi r_n} &\approx \frac{e^{-jkr}}{4\pi r} + \mathbf{e}_n \cdot \nabla_y \left(\frac{e^{-jkr}}{4\pi r} \right) \\ &+ \frac{1}{2} (\mathbf{e}_n \cdot \nabla_y)^2 \left(\frac{e^{-jkr}}{4\pi r} \right) + \dots \end{aligned} \quad (34)$$

where $r = |\mathbf{x} - \mathbf{y}|$. The total sound field can then be written as

$$\begin{aligned} p(\mathbf{x}) &= \left[\sum_{n=1}^N q_n + \left(\sum_{n=1}^N q_n \mathbf{e}_n \right) \cdot \nabla_y \right. \\ &\quad \left. + \frac{1}{2} \sum_{n=1}^N q_n (\mathbf{e}_n \cdot \nabla_y)^2 + \dots \right] \\ &\quad \times \frac{\rho_0 c_0 j k e^{-jkr}}{4\pi r} \end{aligned} \quad (35)$$

where the right side of the equation represents a *multipole expansion* of the source distribution. The first two terms in this series describe, respectively, monopole and dipole sound fields, while the third term describes the radiation from a *quadrupole* source. Particular examples of quadrupole sources are illustrated in Fig. 5a that shows an arrangement of monopole sources that combine to produce a *longitudinal* quadrupole, and in Fig. 5b that shows a source arrangement that defines a *lateral* quadrupole source. In both of these cases the first two summation terms in the above series expansion are zero (this is readily seen by using the values of q_n and \mathbf{e}_n illustrated in Fig. 5). The third term then becomes the leading order term in the series and this can be written as

$$p(\mathbf{x}) = \sum_{\mu=1, v=1}^{\mu=3, v=3} Q_{\mu v} \frac{\partial^2}{\partial y_\mu \partial y_v} \left(\frac{\rho_0 c_0 j k e^{-jkr}}{4\pi r} \right) \quad (36)$$

Figure 5 Coordinate system for the analysis of (a) longitudinal and (b) lateral quadrupole sources.

where the subscripts μ and v define the three coordinate directions (taking the values 1, 2, 3), and the quadrupole strengths are given by

$$Q_{\mu v} = \frac{1}{2} \sum_{n=1}^N \varepsilon_{n\mu} \varepsilon_{nv} q_n \quad (37)$$

where $\varepsilon_{n\mu}$ and ε_{nv} are the components of the vector \mathbf{e}_n in the three coordinate directions. There are nine possible combinations of μ and v that define the strengths $Q_{\mu v}$ of different types of quadrupole source; these are Q_{11} , Q_{22} and Q_{33} all of which are longitudinal quadrupoles, and Q_{12} , Q_{13} , Q_{21} , Q_{23} , Q_{31} , and Q_{32} , which are lateral quadrupoles. Calculation of the sound field radiated involves undertaking the partial derivatives with respect to y_μ and y_v in Eq. (36). It can be shown that in the case of the longitudinal quadrupole depicted in Fig. 5a, where the constituent monopoles lie in a line parallel to the x_1 axis, the sound field reduces to

$$\begin{aligned} p(\mathbf{x}) &= -\frac{\rho_0 c_0 j k^3 e^{-jkr}}{4\pi r} Q_{11} \\ &\times \left[\cos^2 \theta \left(1 + \frac{3}{jkr} + \frac{3}{(jkr)^2} \right) - \frac{1}{jkr} - \frac{1}{(jkr)^2} \right] \end{aligned} \quad (38)$$

where $Q_{11} = q\varepsilon^2$ and $\cos \theta = (x_1 - y_1)/r$. The lateral quadrupole depicted in Fig. 5b has the sound field

$$\begin{aligned} p(\mathbf{x}) &= -\frac{\rho_0 c_0 j k^3 e^{-jkr}}{4\pi r} Q_{12} \\ &\times \left[\cos \theta \sin \theta \cos \phi \left(1 + \frac{3}{jkr} + \frac{3}{(jkr)^2} \right) \right] \end{aligned} \quad (39)$$

where again $Q_{12} = q\epsilon^2$ and $\sin\theta\cos\phi = (x_2 - y_2)/r$, where (r, θ, ϕ) are spherical coordinates centred on the position of the source. The sound fields generated by harmonic lateral and longitudinal quadrupole sources are illustrated in Figs. 6a and 6b. Again, the near fields of the sources, as represented by the terms within the round brackets in Eqs. (38) and (39) that involve the reciprocal of jkr , vanish in the far field as $kr \rightarrow \infty$, and the directivity of the radiation evident in Figs. 6a and 6b is expressed by the terms $\cos^2\theta$ and $\cos\theta\sin\theta\cos\phi$ for longitudinal and lateral quadrupoles, respectively.

It should also be pointed out that, in general, any single point quadrupole source can be regarded as being comprised of nine components whose individual strengths are represented by the terms $Q_{\mu\nu}$. These components are often thought of the elements of a three-by-three matrix, and thus the quadrupole can be defined in terms of a “tensor” strength in much the same way as a point dipole has a three-component “vector” strength.

Figure 6 Single frequency sound fields generated by (a) longitudinal and (b) lateral quadrupole sources.

A longitudinal quadrupole component can also be thought of as being comprised of two point dipoles of equal magnitude but opposite phase that thus apply a fluctuating direct stress to the medium. A simple practical example of such a source is that provided by the vibration of a tuning fork where the two prongs of the fork vibrate out of phase in order to apply a net fluctuating stress to the surrounding medium. No net force is applied and no net volume flow is produced. A lateral quadrupole component on the other hand can be thought of as being comprised of two out-of-phase point dipoles that act in parallel to apply a net fluctuating shear stress to the medium. As explained in more detail in later chapters, these source models form the basis for the analysis of sound generated by unsteady flows and are particularly important for describing the noise radiated by turbulent jets.

CHAPTER 4

SOUND PROPAGATION IN ROOMS

K. Heinrich Kuttruff
Institute of Technical Acoustics
RWTH Aachen University
Aachen, Germany

1 INTRODUCTION

Sound propagation in closed rooms is of interest for several reasons. Not only the acoustical design of large performance halls is of concern but also the acoustical comfort of such environments where people spend most of their lifetimes, either at work in office spaces, workshops, or factories or in homes, hotels, and restaurants. Three different main approaches can be used to describe the complicated sound fields in rooms (Section 2 to 4). The most rigorous and abstract one is based on solutions of the acoustic wave equation, amended by certain conditions that include the shape and the properties of the room boundaries. Here, the sound field is conceived of as being composed of certain elements, named normal modes. Another, conceptually simpler approach to room acoustics, is the geometrical one; it starts with the sound ray and studies the propagation of many rays throughout the room. The acoustical properties of a room can also be discussed in terms of the energy flow. This last method is called the statistical approach. The final section of this chapter is devoted to sound absorption.

2 WAVE ACOUSTICS

2.1 Normal Modes and Eigenfrequencies

The physically exact description of the sound field in a room^{1,2} is based upon the acoustic wave equation. If we assume that the time dependence of the sound pressure p is according to $\exp(j\omega t)$ with ω denoting the angular frequency, this equation transforms into the Helmholtz equation:

$$\nabla^2 p + k^2 p = 0 \quad (1)$$

where $k = \omega/c$ is the angular wave number.

Any solution of this equation has to comply with the acoustical properties of the boundary, that is, of the room walls. These properties can be expressed in terms of the wall impedance, which is defined as the ratio of the acoustic pressure p acting on a given point of the surface and the normal component v_n of the air velocity at the same point:

$$Z = \left(\frac{p}{v_n} \right)_{\text{boundary}} \quad (2)$$

This quantity is usually complex, which indicates that there is a phase difference between p and v_n .

Sometimes, the various elements of the surface react nearly independently from each other to the incident wave. Then the wall or boundary is said to be of the locally reacting type. In this case the normal velocity depends not on the spatial distribution, that is, on the direction of incidence of the primary wave.

The boundary condition can be expressed by the wall impedance Z :

$$Z \frac{\partial p}{\partial n} + j\omega\rho_0 p = 0 \quad (3)$$

In this equation, ρ_0 ($=1.2 \text{ kg/m}^3$ at normal conditions) denotes the density of air, $\partial p/\partial n$ is the component of the sound pressure gradient in the direction of the outward-pointing boundary normal. It should be noted that the wall impedance depends usually on the frequency and may vary from one boundary point to another.

The Helmholtz equation (1) supplemented by the boundary condition (3) can only be solved for certain discrete values k_n of the angular wavenumber k , so-called eigenvalues. (The subscript n stands for three integers according to the three space coordinates.) These values are real if air attenuation (see Section 5.1) is neglected and the wall impedance is purely imaginary, that is, if all walls have mass or spring character, or if it is zero or infinite. Then each eigenvalue is related to a characteristic angular frequency $\omega_n = ck_n$ and hence to a frequency

$$f_n = \frac{ck_n}{2\pi} \quad (4)$$

called the allowed frequency or the eigenfrequency. However, if the impedance of any wall portion has a real component indicating losses, the sound field cannot persist but must die out if there is no sound source making up for the losses. Therefore, the time dependence of the sound pressure must be governed by a factor $\exp(j\omega t - \delta t)$ with δ denoting some decay constant. Then the eigenvalues k_n turn out to be complex, $k_n = (\omega_n + j\delta_n)/c$.

Each eigenvalue is associated with (at least) one solution $p_n(\mathbf{r})$ of Eq. (1) where the vector \mathbf{r} symbolizes the space coordinates. These solutions are called the eigenfunctions or characteristic functions of the room. They correspond to characteristic distributions of the sound pressure amplitude known as normal modes. Each of them can be conceived as a three-dimensional

standing wave with a typical pattern of maxima and minima of the sound pressure amplitude, the minima being situated on certain “nodal surfaces.” If there are no losses the pressure amplitude on these surfaces is zero. In all other cases the standing waves are less pronounced or may even vanish.

Once the eigenfunctions of an enclosure are known, the acoustical response of the room to any type of excitation can be expressed by them, at least in principle. However, the practical use of this formalism is rather limited because closed expressions for the eigenfunctions and eigenfrequencies can be worked out for simply shaped rooms only with rigid walls. In general, one has to resort to numerical methods such as the finite element method, and even then only small enclosures (in relation to the wavelength) can be treated in this way. For larger rooms, either a geometrical analysis based on sound rays (Section 3) or an energy-based treatment of the sound field (Section 4) is more profitable.

2.2 A Simple Example: The Rectangular Room

In this section we consider a rectangular room that is bounded by three pairs of parallel and rigid walls, the walls of each pair being perpendicular to the remaining ones. Expressed in Cartesian coordinates x , y , and z , the room extends from $x = 0$ to $x = L_x$ in the direction of the x axis, from $y = 0$ to $y = L_y$ in y direction, and $z = 0$ to $z = L_z$ in z direction (see Fig. 1).

Since $Z = \infty$ for rigid walls, the boundary condition (3) transforms into

$$\frac{\partial p}{\partial x} = 0 \text{ for } x = 0 \text{ and } x = L_x$$

and two similar equations for the y and the z direction. The Helmholtz equation in Cartesian coordinates reads

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} + k^2 p = 0 \quad (5)$$

Figure 1 Rectangular enclosure.

Its solutions satisfying the boundary conditions are given by

$$p_{n_x n_y n_z}(x, y, z) = A \cos\left(\frac{n_x \pi x}{L_x}\right) \cos\left(\frac{n_y \pi y}{L_y}\right) \times \cos\left(\frac{n_z \pi z}{L_z}\right) \quad (6)$$

Here A is an arbitrary constant, and n_x , n_y , and n_z are integers. The associated angular eigenfrequency $\omega_{n_x n_y n_z}$ is $ck_{n_x n_y n_z}$ with

$$k_{n_x n_y n_z} = \pi \sqrt{\left(\frac{n_x}{L_x}\right)^2 + \left(\frac{n_y}{L_y}\right)^2 + \left(\frac{n_z}{L_z}\right)^2} \quad (7)$$

According to Eq. (6) the nodal surfaces are equidistant planes parallel to the room walls.

Figure 2 shows curves of constant sound pressure amplitude ($|p/p_{\max}| = 0.2, 0.4, 0.6$, and 0.8) in the plane $z = 0$ for $n_x = 3$ and $n_y = 2$. The dotted lines are the intersections of two systems of equidistant nodal planes with the bottom $z = 0$, they separate regions in which the instantaneous sound pressure has opposite signs.

The number of eigenfrequencies within the frequency range from zero to an upper limit f can be estimated by

$$N_f \approx \frac{4\pi}{3} V \left(\frac{f}{c}\right)^3 + \frac{\pi}{4} S \left(\frac{f}{c}\right)^2 + \frac{L}{8} \left(\frac{f}{c}\right) \quad (8)$$

In this expression V and S are the volume of the room and the area of its boundary, respectively, and $L = 4(L_x + L_y + L_z)$. It is noteworthy that its first term is valid for any enclosure. The same holds for

Figure 2 Normal mode in a rectangular enclosure (see Fig.1): Curves of equal sound pressure amplitude in a plane perpendicular to the z axis ($n_x = 3, n_y = 2$).

the average spacing of adjacent eigenfrequencies as derived from that term:

$$\langle \delta f \rangle \approx \frac{c^3}{4\pi V f^2} \quad (9)$$

According to these equations, a room with a volume of 1000 m³ has more than 100 million eigenfrequencies in the frequency range from 0 to 10,000 Hz; their average spacing at 1000 Hz is as small as about 0.003 Hz!

Of course, a rectangular room with perfectly rigid walls is never encountered in reality. Nevertheless, Eq. (6) is still a good approximation to the true pressure distribution even if there are losses, provided they are not too high. If the wall impedance is finite but purely imaginary, the eigenvalues k_n are still real but different from those in Eq. (7), particularly the lowest ones. Similarly, the nodal planes are still equidistant, but their locations are different from those of the rigid room.

To get an idea of the influence of losses we denote with Z_x the impedance of the walls perpendicular to the x axis, and similarly Z_y and Z_z , and we assume that these impedances are real and finite but still large compared to the characteristic impedance $\rho_0 c$ of air (c = sound velocity). Then the eigenvalues are approximately

$$k_n \approx k'_n + j \frac{2\rho_0 \omega}{k'_n} \left(\frac{1}{L_x Z_x} + \frac{1}{L_y Z_y} + \frac{1}{L_z Z_z} \right) \quad (10)$$

with $k'_n \approx k_{n_x, n_y, n_z}$ after Eq. (7). As stated in Section 2.1, the imaginary part of k_n in Eq. (10) is related to the decay constant δ_n .

2.3 Steady-State Sound Field

If all eigenvalues $k_n = (\omega_n + j\delta_n)/c$ and the associated eigenfunctions $p_n(\mathbf{r})$ are known for a given enclosure, the complex sound pressure amplitude in any inner point \mathbf{r} can be expressed in terms of them. Let us suppose that the room is excited by a point source at a location \mathbf{r}' operated at an angular frequency ω . Then, under the assumption $\omega_n \gg \delta_n$, the complex sound pressure amplitude in \mathbf{r} can be represented by the expression

$$p_\omega(\mathbf{r}) = C \sum_{n=0}^{\infty} \frac{\omega p_n(\mathbf{r}) p_n(\mathbf{r}')}{K_n (\omega^2 - \omega_n^2 - 2j\delta_n \omega_n)} \quad (11)$$

The constant C is proportional to the strength of the sound source; K_n is a normalization constant. The function $p_\omega(\mathbf{r})$ can be conceived as the transfer function of the room between the points \mathbf{r} and \mathbf{r}' . Each term of the sum represents a resonance of the enclosure with the angular resonance frequency ω_n . Whenever the driving frequency ω coincides with one of the eigenfrequencies ω_n , the contribution of the corresponding term will reach its maximum.

Concerning the frequency dependence of the pressure amplitude, two limiting cases have to be distinguished: At low frequencies the mean spacing

$\langle \delta f \rangle$ of eigenfrequencies after Eq. (9) is substantially larger than the average half-width $\langle \Delta f \rangle = \langle \delta \rangle / 2\pi$ of the resonance curves with $\langle \delta \rangle$ denoting an average decay constant. Then the transfer function $p_\omega(\mathbf{r})$ of the enclosure consists of an irregular succession of well-separated resonance curves, accordingly each normal mode can clearly be observed. At high frequencies, however, $\langle \delta f \rangle$ is much smaller than $\langle \Delta f \rangle$, hence many eigenfrequencies are lying within the half-width of each resonance curve. In other words, the resonance curves will strongly overlap and cannot be separated. When the room is excited with a sine tone, not just one but several or many terms of the sum in Eq. (11) will give significant contributions to the total sound pressure $p_\omega(\mathbf{r})$.

The characteristic frequency that separates both frequency regions is the so-called *Schroeder frequency*³:

$$f_s = \frac{5000}{\sqrt{V \langle \delta \rangle}} \approx 2000 \sqrt{\frac{T}{V}} \quad (12)$$

where T denotes the reverberation time of the room (see next subsection). For a living room with a volume $V = 50$ m³ and a reverberation time $T = 0.5$ s, this frequency is about 200 Hz. We can conclude from this example that isolated modes will turn up only in small enclosures such as bathrooms, passenger cars, or truck cabins.

The more typical situation in room acoustics is that of strong modal overlap, characterized by $f > f_s$. In this case $p_\omega(\mathbf{r})$ can be considered as a random function of the frequency with certain general properties, some of which will be described below. Logarithmic representations or recordings of $|p_\omega(\mathbf{r})|$ are often referred to as *frequency curves* in room acoustics. Figure 3 shows a slice of such a frequency curve obtained in the range from 1000 to 1100 Hz. The irregular shape of this curve is typical for all rooms, no matter where the sound source or the receiving point is located; the only condition is that the distance between both points exceeds the reverberation distance [see Eq. (27)]. A frequency curve shows a maximum

Figure 3 Portion of a frequency curve, ranging from 1000 to 1100 Hz.

whenever many contributions to the sum in Eq. (11) happen to have about the same phase. Similarly, a minimum appears if most of these contributions cancel each other. It can be shown³ that the mean spacing between adjacent maxima of a frequency curve is about

$$\langle \delta f_{\max} \rangle \approx \frac{\langle \delta \rangle}{\sqrt{3}} \approx \frac{4}{T} \quad (13)$$

Furthermore, the magnitude $|p|$ of the sound pressures in a room follows a Rayleigh distribution: Let q denote $|p|$ divided by its average; then the probability that this quantity lies within the interval from q to $q + dq$ is given by

$$P(q) dq = \frac{\pi}{2} \exp\left(-\frac{\pi q^2}{4}\right) q dq \quad (14)$$

This distribution is plotted in Fig. 4. It should be pointed out that it holds not only for one particular frequency curve but as well for all levels encountered in a room at a given frequency. It tells us that about 70% of the levels are contained within a 10-dB range around their average value.

2.4 Transient Response: Reverberation

As already noted in Section 2.1, any normal mode of an enclosure with complex wall impedance will decay unless a sound source compensates for the wall losses. Therefore, if a sound source is abruptly stopped at time $t = 0$, all excited normal modes will die out with their individual damping constants δ_n . Accordingly, if we assume $\omega_n \gg \delta_n$ as before, the sound pressure at any point can be expressed by

$$p(t) = \sum_{n=0}^{\infty} a_n e^{-\delta_n t} e^{j\omega_n t} \quad \text{for } t \geq 0 \quad (15)$$

Figure 4 Rayleigh distribution, indicating the probability density of sound pressure amplitudes in a room. The abscissa is $q = |p|/\langle |p| \rangle$.

The complex coefficients a_n contain the eigenfunctions $p_n(\mathbf{r})$ and depend on the location of the sound source and the signal it emits. Equation (15) describes what is called the reverberation of a room.

Very often the decay constants δ_n are not too different from each other and may therefore be replaced without much error by their mean value $\langle \delta \rangle$. Then the energy density at a certain point of the sound field will decay at a uniform rate:

$$\varepsilon(t) = \varepsilon_0 e^{-2\langle \delta \rangle t} \quad \text{for } t \geq 0 \quad (16)$$

In room acoustics, the duration of sound decay is usually characterized by the *reverberation time*, or the *decay time*, T , defined as the time interval in which the sound energy or energy density drops to one millionth of its initial value, or the sound pressure level decreases by 60 dB. From Eq. (16) it follows that

$$T = \frac{3 \ln 10}{\langle \delta \rangle} \approx \frac{6.91}{\langle \delta \rangle} \quad (17)$$

The reverberation time is one of the most important quantities in room acoustics. It can be measured with good accuracy, and the available formulas (see Section 4.3) predict it quite well.

3 GEOMETRIC ACOUSTICS

Although the formal treatment as outlined in the preceding section yields many important insights into sound propagation in rooms, the geometrical approach is more closely related to our imagination. It is based not on the concept of waves but on the notion of sound rays, and it considers mere energy propagation. Accordingly, all phase effects such as interference or diffraction are neglected. This simplification is permissible if the sound signal is composed of many spectral components covering a wide frequency range. Then it can be assumed that all constructive or destructive phase effects cancel each other when two or more sound field components are superimposed at a point, and the total energy at it is simply obtained by adding their energies. Components with this property are often referred to as *incoherent*.

A sound ray can be thought of as a small sector subtending a vanishingly small solid angle that is cut out of a spherical wave. Usually, it is pictured as a straight line provided the medium is homogeneous. Along these lines the sound energy travels with constant velocity, and from the definition of a ray it follows that the total energy carried by it is independent on the distance it has traveled provided the medium is free of dissipation. The intensity along a sound ray, however, decreases proportionally to $1/r^2$, where r denotes the distance from the sound source.

Furthermore, we assume that all sound reflecting objects, in particular all walls of a room, are large compared to the acoustic wavelength. Then the reflection of sound obeys the same law as the reflection of light in geometrical optics. As an exception we shall

consider in Section 3.2 diffuse reflections from walls with many surface irregularities.

3.1 Sound Reflection and Image Sources

When a sound wave represented as a ray falls upon a plane and smooth wall of infinite extension, it will be “specularly” reflected from it. This means that the angle under which the reflected ray leaves the wall equals the angle of incidence where both angles are measured against the wall normal (see Fig. 5); furthermore, the incident ray, the reflected ray, and the wall normal are situated in the same plane. This law can also be applied to walls of finite size provided their dimensions are large compared to the acoustic wavelength so that diffraction effects from the edges can be neglected.

If the incident ray is emitted by a point source, the reflected ray can be thought of as originating from a virtual sound source that is the mirror image of the original source with respect to the reflecting wall as also shown in Fig. 5. This secondary source, which is assumed to emit the same signal as the original one, is called an *image source*. The idea of image sources is particularly useful for constructing the reflection of a ray bundle from a plane wall portion or for finding the sound path that connects a given source and receiving point, including reflection from a wall. Its full potential is developed, however, in the discussion of sound propagation in enclosures.

Because of the wall losses, only a fraction of the incident sound energy will be reflected from the wall. This can be accounted for by the absorption coefficient α of the wall, defined as the fraction of incident sound energy absorbed by the wall. Accordingly, the reflection process reduces the energy of the sound ray by the factor $1 - \alpha$. This is tantamount to operating the image source at a power reduced by this factor. If the sound source has a certain directivity, the

symmetrically inverted directivity pattern must be assigned to the image source.

If a reflected sound ray strikes a second wall, the sound path can be found by repeating the mirroring process, that is, a second image source is constructed that is the mirror image of the first one with respect to the second wall. This is illustrated by Fig. 6, which depicts an edge formed by two adjacent plane walls. In addition to the two first-order image sources A'_1 and A'_2 , there are two second-order image sources A''_1 and A''_2 . It should be noted that there is no path connecting the source with the receiving point R via A''_2 and some first-order image source. This example shows that certain image sources may turn out to be “invisible,” that is, they are not valid. This happens whenever a ray intersects the plane of a wall outside its physical extension.

A regular array of image sources is formed by two parallel infinite planes with distance h as depicted in Fig. 7. This “enclosure” can be regarded as a model of many factory spaces or of open-plan bureaus the height of which is small compared to their lateral dimensions. Since most points are not close to a side wall, the contributions of the latter can be neglected. The image sources of this flat room are arranged along a vertical line; they are equidistant, if the primary source lies exactly in the middle between the floor and the ceiling.

For a space that is completely surrounded by plane walls, mirroring may be repeated over and over, leading to images of increasing order. These images form a three-dimensional pattern that depends on the geometry of the enclosure. However, most of these image sources are invisible from a given observation point. Several algorithms have been developed by which the visibility or validity of image sources can be checked.^{4,5} (An exception is the rectangular room, its image sources form a regular three-dimensional

Figure 5 Sound reflection from a plane wall: A original source, A' image source, R receiving point.

Figure 6 Sound reflections from an edge formed by two adjacent walls: A original sound source, A' first-order image sources, A'' second-order image sources, R receiving point.

Figure 7 Flat room with original sound source A and image sources A_n ; R receiving point.

pattern, and all of them are visible from all positions within the original enclosure.)

Once all valid images up to a certain order (or strength) are known, the boundary itself is no longer needed; the energy density at a certain point of the room is obtained just by adding the contributions of all visible image sources provided they are not too faint. The effect of air attenuation is easily included if desired (see Section 5.1).

In this way, not only the steady-state energy density but also transient processes can be studied. Suppose the original sound source would produce the energy density $\varepsilon(t)$ at some point of the free space. In a room, each image source will emit a weaker replica of this energy signal, provided the absorption of the boundary is frequency independent. At a given receiving point, it will appear with some delay τ_n depending on its distance from the image source. Thus the total energy signal observed at the receiving point is

$$\varepsilon'(t) = \sum_n b_n \varepsilon(t - \tau_n) \quad (18)$$

with the coefficients b_n characterizing the relative strengths of the different contributions.

If $\varepsilon(t)$ is an impulse with vanishingly short duration, the result of this superposition is the energetic impulse response of the enclosure for a particular source–receiver arrangement as shown in Fig. 8. In this diagram, each contribution to the sum in Eq. (18) is represented by a vertical line the length of which is proportional to its energy. The first line marks the “direct sound component,” contributed by the original sound source. The abscissa in Fig. 8 is the delay of the reflected components with respect to the direct sound. Although this diagram is highly idealized, it shows that usually most of the sound energy received at some point in a room is conveyed by image sources, that is, by wall reflections. Experimentally obtained impulse responses differ from this simple scheme since real walls have frequency-dependent acoustical properties and hence change the form of the reflected signal. Generally, the impulse response can be regarded as the *acoustical fingerprint* of a room.

3.2 Enclosures with Curved or Diffusely Reflecting Walls

The concept of image sources is a valuable tool in the acoustical design of rooms, and several commercially available computer programs are based upon it. However, it cannot be applied to curved walls, although the laws of specular reflection are still valid for such surfaces as long as all their dimensions including the radius of curvature are large compared to the wavelength. In some cases, the laws of concave or convex mirrors as known from optics can be used to study the effect of such surfaces.² In general, however, the reflected sound rays must be found by constructing the wall normal in each wall point of interest and applying the reflection law separately to each them.

The idea of image sources fails too when the surface of a wall is not smooth but has a certain structure, which is quite often the case. If the dimension of the nonuniformities is comparable to the sound wavelength, the wall does not reflect the arriving sound according to the above-mentioned law but scatters it into different directions. About the same happens if a wall has nonuniform impedance. Walls with irregularly distributed nonuniformities produce what is called

Figure 8 Energetic impulse response of a room (schematically).

diffuse reflections in room acoustics. It is obvious that diffusely reflecting walls make the sound field in a room much more uniform. This is believed to be one of the reasons why many old concert halls with their molded wall decorations, pillars, columns, statuettes, coffered ceilings, and the like are well-known for their excellent acoustics. In modern halls, walls are often provided with recesses, boxes, and the like in order to achieve similar effects. Particularly effective devices in this respect are *Schroeder* diffusers consisting of a series of wells the depths of which are chosen according to certain number-theoretic schemes.⁶

In the limit of very strong scattering it is admissible and convenient to apply Lambert's law, according to which the scattered intensity is proportional to the cosine of the scattering angle ϑ , that is, the angle between the wall normal and the direction into which the sound is scattered:

$$dI(r, \vartheta) = P_s \frac{\cos \vartheta}{\pi r^2} \quad (19)$$

where P_s is the total power scattered by the reflecting wall element dS , and r is the distance from it.

If the boundary of an enclosure scatters the arriving sounds everywhere according to Eq. (19), an analytical method, the so-called radiosity method can be used to find the steady-state energy distribution in the enclosure as well as its transient behavior. This method is based on a certain integral equation and is described elsewhere.^{7,8}

A more general way to determine the sound field in an enclosure the boundary of which produces at least partially diffuse reflections is *ray tracing*.^{9,10} The easiest way to understand these techniques is by imagining hypothetical sound particles that act as the carriers of sound energy. These particles are emitted by the sound source, and they travel with sound velocity along straight lines until they arrive at a wall. Specularly reflected particles will continue their way according to the law of specular reflection. If a particle is scattered from the boundary, its new direction is determined by two computer-generated random numbers in such a way, that the azimuth angle is uniformly distributed while the distribution of the angle ϑ must follow Eq. (19). In any case, wall absorption is accounted for by reducing the energy of a reflected particle by a factor $1 - \alpha$ with α denoting the absorption coefficient. The final result is obtained by adding the energies of all particles crossing a previously assigned counting volume considered as the "receiver." Classifying the arrival times of the particles yields the energetic impulse response for the chosen receiving position.

4 STATISTICAL ROOM ACOUSTICS

4.1 Diffuse Sound Field

In this section closed formulas for the energy density in an enclosure both at steady-state conditions and during

sound decay are presented. Such expressions are of considerable importance in practical room acoustics. They are used to predict noise levels in working environments or to assess the suitability of a room for the different types of performances.

The approach we are using here is based on the energy balance:

$$P(t) = \frac{d}{dt} \int_V \varepsilon dV + E_{\text{abs}} \quad (20)$$

where V is the room volume and E_{abs} denotes the energy that the boundary absorbs per second; $P(t)$ is the power supplied to the room by some sound source, and ε is the energy density. This equation tells us that one part of the input energy is used to change the energy content of the room, whereas the other one is dissipated by the boundary.

Generally, the relation between the energy density and the absorbed energy E_{abs} is quite involved. It is simple, however, if the sound field in the room can be assumed as *diffuse*. This means that at each point inside the boundary the sound propagation is uniformly distributed over all directions. Accordingly, the total intensity vector in a diffuse field would be zero. In real rooms, however, the inevitable wall losses "attract" a continuous energy flow originating from the sound source; therefore, the intensity vector cannot completely vanish. At best we can expect that a sound field is sufficiently diffuse to permit the application of the properties to be outlined below.

Generally, the degree of sound field diffusion depends on the shape of the room. In an irregular polyhedron room there will certainly be stronger mixing of sound rays than in a sphere or another regularly shaped enclosure. Another important factor is the kind of boundary. The energy distribution—both spatial and directional—will be more uniform if the walls are not smooth but produce diffuse reflections by some scattering (see preceding subsection). And finally the degree of sound field diffusion is influenced by the amount and distribution of wall absorption. Usually, diffusion is the higher the smaller is the total absorption and the more uniformly it is distributed over the boundary. It should be emphasized that the condition of a diffuse sound field must be clearly distinguished from diffuse wall reflections; the latter usually increase the degree of sound field diffusion, but they do not guarantee it.

An important property of a diffuse sound field is the constancy of its energy density throughout the whole room. Furthermore, it can be shown that the energy B hitting the boundary per second and unit area is also constant along the boundary and is related to the energy density ε by

$$B = \frac{c}{4} \varepsilon \quad (21)$$

To give Eq. (20) a useful form, it is convenient to introduce the *equivalent absorption area* or the total

absorption of the room:

$$A = \iint_S \alpha dS \text{ or } A = \sum_i S_i \alpha_i \quad (22)$$

The latter expression is applicable if the boundary consists of several finite portions with constant absorption coefficients α_i ; their areas are S_i . Since the sound field is assumed as diffuse, the absorption coefficient in this and the following expressions is identical with the absorption coefficient α_d for random sound incidence to be defined in Eq. (35).

Now the total energy E_{abs} absorbed per second can be expressed as $AB = (c/4)A\varepsilon$. Then Eq. (20) becomes a simple differential equation of first order:

$$V \frac{d\varepsilon}{dt} + \frac{cA}{4}\varepsilon = P(t) \quad (23)$$

which is easily solved for any time-dependent power output $P(t)$.

The equivalent absorption area has the dimension of square metres and can be imagined as the area of a totally absorbing boundary portion, for instance, of an open window with area A in which the total absorption of the enclosure is concentrated.

4.2 Stationary Energy Density

At first we consider a sound source with constant power output P ; accordingly the energy density will also be constant and the time derivative in Eq. (23) is zero. Hence the steady-state energy density $\varepsilon_s = \varepsilon$ is

$$\varepsilon_s = \frac{4P}{cA} \quad (24)$$

For practical purposes it is convenient to convert the above relation into the logarithmic scale and thus to relate the sound pressure level L_p with the sound power level $L_W = 10 \cdot \log_{10}(P/P_0)$ ($P_0 = 10^{-12}$ W):

$$L_s = L_W - 10 \cdot \log_{10} \left(\frac{A}{1\text{m}^2} \right) + 6 \text{ dB} \quad (25)$$

This relation is frequently used to determine the total sound power output P of a sound source by measuring the stationary sound pressure level. The equivalent absorption area A of the enclosure is obtained from its reverberation time (see next section). Furthermore it shows to which extent the noise level in workshops, factory halls, or open-plan bureaus can be reduced by providing the ceiling and the side walls with some sound-absorbing lining.

Equations (24) and (25) represent the energy density and the sound pressure level in what is called the diffuse or the reverberant field. This field prevails when the distance r of the observation point from the sound source is relatively large. In the vicinity of the

sound source, however, the direct sound component is predominant. For a nondirectional sound source the energy density of this latter component is

$$\varepsilon_d = \frac{P}{4\pi cr^2} \quad (26)$$

In a certain distance, the so-called reverberation distance r_r , both components, namely the direct and the reverberant part of the energy density, are equal:

$$r_r = \frac{1}{4} \sqrt{\frac{A}{\pi}} \approx 0.057 \sqrt{\frac{V}{T}} \quad (27)$$

Here T is the reverberation time already introduced in Section 2.4. According to this formula, the reverberation distance r_r in a hall with a volume of 10,000 m³ and a reverberation time $T = 2$ s is about 4 m. The total energy density ε_t is given by

$$\varepsilon_t = \varepsilon_d + \varepsilon_s = \frac{P}{4\pi cr^2} \left(1 + \frac{r^2}{r_r^2} \right) \quad (28)$$

The above relations should be applied with some caution. For signals with narrow frequency bandwidth they yield at best an average or expectation value of ε since we know from Section 2.3 that the stationary sound pressure amplitude in an enclosure is far from being constant but is distributed over a wide range. The same holds true for the energy density. Even for wide-band excitation, the energy density is usually not completely constant throughout the room. One particular deviation¹¹ is due to the fact that any reflecting wall enforces certain phase relations between incident and reflected waves no matter from which directions they arrive. As a consequence, the energy density in a diffuse field shows spatial fluctuations in the vicinity of a wall depending on its acoustical properties and on the frequency spectrum of the sound signal. Right in front of a rigid wall, for instance, the energy density is twice its average value far away from it. In the high-frequency limit, these deviations can be neglected.

4.3 Sound Decay

For the discussion of decaying sound fields we imagine a sound source exciting the enclosure up to the time $t = 0$ when it is abruptly stopped. (As an alternative, sound decay can be produced by a short impulse emitted at $t = 0$.) If the sound field is sufficiently diffuse, Eq. (23) can be applied with $P = 0$. The solution of this differential equation is

$$\varepsilon(t) = \varepsilon_0 \exp \left(-\frac{cA}{4V}t \right) \quad \text{for } t \geq 0 \quad (29)$$

which agrees with Eq. (16) if we set $\langle \delta \rangle = cA/8V$. The symbol ε_0 denotes the initial energy density at $t = 0$. From this equation, the reverberation time T of the enclosure, that is, the time in which the energy density

has dropped by a factor of 10^6 (see Section 2.4) is easily obtained:

$$T = \frac{24 \cdot \ln 10}{c} \cdot \frac{V}{A} = 0.163 \frac{V}{A} \quad (30)$$

In these expressions all lengths must be expressed in metres.

Equation (30) is the famous Sabine reverberation formula¹² and is probably the most important relation in room acoustics. Despite its simplicity, its accuracy is sufficient for most practical purposes provided the correct value for the equivalent absorption A is inserted. However, it fails for enclosures with high absorption: for a perfectly absorbing boundary ($A = S$) it still predicts a finite reverberation time although in this case there would be no reverberation at all.

A more rigorous derivation leads to another decay formula that is free of this defect:

$$T = 0.163 \frac{V}{-S \ln(1 - \langle \alpha \rangle)} \quad (31)$$

This relation is known as Eyring's formula,¹³ although it was first described by *Fokker* (1924). It is obvious that it yields the correct reverberation time $T = 0$ for a totally absorbing boundary. For $\langle \alpha \rangle \ll 1$ it becomes identical with Sabine's formula, Eq. (30).

Sound attenuation in air can be taken into account by adding a term $4mV$ to the denominator of Eq. (30) or (31), leading to

$$T = 0.163 \frac{V}{4mV + A} \quad (30a)$$

and

$$T = 0.163 \frac{V}{4mV - S \ln(1 - \langle \alpha \rangle)} \quad (31a)$$

In both expressions, m is the attenuation constant of air, which will be explained in more detail in Section 5.1, where numerical values of m will be presented.

The content of these formulas may be illustrated by a simple example. We consider a hall with a volume of $V = 15000 \text{ m}^3$, the total area S of its walls (including the ceiling and the floor) is 4200 m^2 . The area occupied by the audience amounts to 800 m^2 , its absorption coefficient is 0.9 (at medium sound frequencies, say 500 to 1000 Hz) while the absorption coefficient of the remaining part of the boundary is assumed to be 0.1. This leads to an equivalent absorption area A of 1060 m^2 , accordingly the average absorption coefficient $A/S = \langle \alpha \rangle$ is 0.252 and $-\ln(1 - \langle \alpha \rangle) = 0.29$. With these data Eq. (30) yields a reverberation time of 2.3 s. The decay time after Eyring's formula Eq. (31) is somewhat smaller, namely 2.0 s. Including air attenuation according to

Eq. (31a) with $m = 10^{-3}$ would reduce the latter value to about 1.9 s.

It should be recalled that the derivation of all the formulas presented in this and the preceding section was based upon the assumption of diffuse sound fields. On the other hand, sound fields in real rooms fulfill this condition at best approximately as was pointed out in Section 4.1. Particularly strong violations of the diffuse field condition must be expected in very long or flat enclosures, for instance, or if the boundary absorption is nonuniformly distributed. A typical example is an occupied auditorium where most of the absorption is concentrated onto the area where the audience is seated. In fact, the (average) steady-state energy density in a fully occupied concert hall is not constant in contrast to what Eq. (24) or Eq. (28) predicts for $r \gg r_r$. Nevertheless, experience has shown that the reverberation formulas presented in this section yield quite reasonable results even in this case. Obviously, the decay process involves mixing of many sound components, and hence the relations derived in this subsection are less sensitive to violations of the diffuse field condition.

5 SOUND ABSORPTION

5.1 Air Attenuation

All sound waves are subject to attenuation by the medium in which they are propagated. In air, this effect is not very significant at audio frequencies, therefore it is often neglected. Under certain conditions, however, for instance, in large halls and at elevated frequencies, it becomes noticeable.

The attenuation by air has several reasons: heat conductivity and viscosity, and in particular certain relaxation processes that are caused by the molecular structure of the gases of which air consists.

A plane sound wave traveling along the x axis of a Cartesian coordinate system is attenuated according to

$$I(x) = I_0 \exp(-mx) \quad (32)$$

or, expressed in terms of the sound pressure level:

$$L(x) = L_0 - 4.34mx \quad (\text{dB}) \quad (33)$$

According to the various processes involved in attenuation, the attenuation constant m shows a complicated frequency dependence, furthermore it depends on the temperature and the humidity of the air. Table 1 lists some values of m in air.

5.2 Absorption Coefficient and Wall Impedance

In Section 3.1 the absorption coefficient of a boundary was introduced as the fraction of incident sound energy that is not reflected by it. Usually, this quantity depends on the frequency and on the incidence

Table 1 Attenuation Constant of Air at 20°C and Normal Atmospheric Pressure, in 10^{-3} m^{-1} .

Relative Humidity (%)	Frequency (kHz)						
	0.5	1	2	3	4	6	8
40	0.60	1.07	2.58	5.03	8.40	17.71	30.00
50	0.63	1.08	2.28	4.20	6.84	14.26	24.29
60	0.64	1.11	2.14	3.72	5.91	12.08	20.52
70	0.64	1.15	2.08	3.45	5.32	10.62	17.91

After Ref. 14.

angle ϑ . It is related to the more general wall impedance Z as defined in Eq. (2) by

$$\alpha(\vartheta) = 1 - \left| \frac{Z \cos \vartheta - \rho_0 c}{Z \cos \vartheta + \rho_0 c} \right|^2 \quad (34)$$

If the boundary reacts locally to an incoming wave (see Section 2.1), the wall impedance does not depend on the direction of sound incidence; hence the only angle dependence of $\alpha(\vartheta)$ is that of the cosine function. If furthermore $|Z| > \rho_0 c$ as is usually the case, the absorption coefficient grows at first when ϑ is increased; after reaching a maximum it diminishes and finally becomes zero at grazing incidence ($\vartheta = \pi/2$).

Since in most enclosures the sound field can be regarded as more or less diffuse, it is useful to assign an averaged absorption coefficient to the boundary, calculated according to *Paris'* formula:

$$\alpha_d = \int_0^{\pi/2} \alpha(\vartheta) \sin(2\vartheta) d\vartheta \quad (35)$$

For a locally reacting surface α_d can be directly calculated after inserting Eq. (34). The result is presented in Fig. 9. This diagram shows contours of constant absorption coefficient α_d . Its abscissa and ordinate are the phase angle β and the magnitude, respectively, of the "specific wall impedance"

$$\zeta = |\zeta| \exp(j\beta) = \frac{Z}{\rho_0 c} \quad (36)$$

respectively. It is noteworthy that α_d has an absolute maximum 0.951 for the specific impedance $\zeta = 1.567$, that is, it will never reach unity.

5.3 Types of Sound Absorbers

After this more formal description of sound absorption a brief account of the various sorts of sound-absorbing devices will be presented.

5.3.1 Absorption by Yielding Walls The simplest case of a sound-absorbing boundary is a wall that is set into motion as a whole by the pressure variations of the sound field in front of it. The wall emits

Figure 9 Curves of equal absorption coefficient of a locally reacting surface for random sound incidence. The abscissa and the ordinate are the phase angle β and the magnitude, respectively, of the specific wall impedance $\zeta = Z/\rho_0 c$.

a secondary sound wave into the outer space; hence "absorption" is not caused by dissipation but by transmission. Therefore, the well-known mass law of sound transmission through walls applies according to which the absorption coefficient at normal sound incidence is:

$$\alpha(0) \approx \left(\frac{2\rho_0 c}{\omega m'} \right)^2 \quad (37)$$

Here m' is the "specific mass," that is, the mass per unit area of the boundary. This approximation is permissible if $2\rho_0 c/\omega m'$ is small compared with unity, which is usually the case. At random sound incidence the absorption coefficient is about twice the above value.

Practically this type of absorption occurs only at low frequencies and with light walls such as thin windows or membranes.

5.3.2 Absorption by Porous Materials Commonly used sound absorbers comprise porous materials. The absorption is brought about by pressure differences or pressure gradients that enforce airflows within the pores. The losses are caused by internal friction (viscosity) and by heat conduction between the air and the pore walls. By both processes motional energy is irreversibly transformed into heat. The absorption depends on the sort, the dimensions of the material, and on the way it is exposed to the sound field.

At first we consider a thin porous sheet, a curtain, for instance. Suppose at both its sides are different pressures p and p' . Then the flow resistance characterizing the material is

$$r_s = \frac{p - p'}{v_s} \quad (38)$$

with v_s denoting the velocity of the airflow enforced by the pressure difference $p - p'$.

Another characteristic quantity is the specific mass m' of the sheet. If the curtain is exposed to a sound wave with an angular frequency well below $\omega_s = r_s/m'$, it will move as a whole and the airflow forced through the pores will be small. For frequencies much larger than ω_s , however, the curtain stays at rest because of its inertia; the velocity at its surface is entirely due to the air passing the material. In the latter case, the absorption coefficient of the curtain may become quite noticeable even if the curtain is freely hanging; its maximum is 0.446 occurring when $r_s = 3.14\rho_0 c$.

The situation is different when the curtain or the fabric is arranged in front of a rigid wall with some airspace in between. At normal sound incidence, a standing wave will be formed in the airspace with a velocity node at the wall. The absorption coefficient shows strong and regular fluctuations. It vanishes whenever the depth is an integer multiple of the sound wavelength. In the frequency range between two of these zeros it assumes a maximum:

$$\alpha_{\max} = \frac{4\rho_0 c r_s}{(r_s + \rho_0 c)^2} \quad (39)$$

The strong frequency of the absorption coefficient can be prevented by arranging the curtain in deep folds.

Most sound absorbers consist of a layer of porous materials, for instance, of rockwool, glass fiber, or plastic foam. Again, the properties of the layer is characterized by the flow resistance r_s . Another important parameter is the porosity σ defined as the volume fraction of the voids in the material.

In Fig. 10a we consider a homogeneous layer of porous material right in front of a rigid wall. When a sound wave arrives perpendicularly at this arrangement, one portion of it is reflected from the

Figure 10 Various types of porous absorbers. (a) Porous layer in front of a rigid wall, (b) same, with airspace behind the layer, (c) as in (b), with perforated panel in front of the layer, (d) as in (b), with airspace partitioned.

front face while the other one will intrude into the material. If the interior attenuation is high, this part will die out after a short traveling distance. Otherwise, a more or less pronounced standing wave will be formed in the material that leads to fluctuations of the absorption coefficient as in the case considered before. When the thickness d of the layer is small compared with the acoustic wavelength, that is, at low frequencies, its absorption coefficient is small because all the porous material is situated close to the velocity node next to the rigid wall.

This behavior is illustrated by Fig. 11, which shows the absorption coefficient for normal sound incidence of an arrangement after Fig. 10a. The active material is assumed to consist of many fine and equidistant channels in a solid matrix (Rayleigh model), the porosity σ is 0.95. The abscissa of the diagram is the product fd of the frequency and the thickness of the layer in metres, the parameter is the fraction $r_s/\rho_0 c$. High absorption coefficients are

Figure 11 Absorption coefficient of a layer according to Fig. 15a (Rayleigh model, $\sigma = 0.95$, normal sound incidence). fd in Hz m, curve parameter: $r_s/\rho_0 c$. (From Ref. 2).

achieved if $r_s/\rho_0 c$ is in the range of 1 to 4 and the product fd exceeds 30 Hz m.

The range of high absorption can be significantly extended toward lower frequencies by mounting the active layer in some distance from the rigid wall as shown in Fig. 10b, that is, by avoiding the region of low particle velocity.

In practical applications, a protective layer must be arranged in front of the porous material to keep humidity away from it and, at the same time, to prevent particles from polluting the air in the room. The simplest way to do this is by wrapping the porous material into thin plastic foils. Protection against mechanical damage is often achieved by a perforated facing panel made of metal, wood, or plastic (see Fig. 10c). In any case, the protective layer acts as a mass load that reduces the absorption of the whole arrangement at high frequencies.

At oblique sound incidence, sound waves can propagate within a porous material parallel to its surface. The same effect occurs in an air backing. Hence this type of absorber is generally not locally reacting. Its performance can be improved, however, by partitioning the airspace as shown in Fig. 10d.

5.3.3 Resonance Absorbers A panel arranged in front of a rigid wall with some airspace in between acts as a resonance absorber. The panel may be unperforated and must be mounted in such a way that it can perform bending vibrations under the influence of an arriving sound wave. The motion of the panel is controlled by its specific mass m' and by the stiffness of the air cushion behind it. (The bending stiffness of the panel is usually so small that its influence on the resonance frequency is negligible.) As an alternative, a sparsely perforated panel may be employed to which the specific mass

$$m' = \frac{\rho_0}{\sigma} \left(h + \frac{\pi}{2} a \right) \quad (40)$$

can be attributed. Here h is the thickness of the panel, a is the radius of the holes, and σ is their fractional area. In both cases the resonance frequency and hence the frequency, at which the absorber is most effective, is

$$f_0 \approx \frac{c}{2\pi} \sqrt{\frac{\rho_0}{m'D}} \quad (41)$$

with D denoting the thickness of the airspace. Sound absorption is caused by elastic losses in the panel if this is unperforated, or, for a perforated panel, by viscous losses in the apertures. It can be increased by arranging some porous material in the airspace.

Figure 12 shows an example of a panel absorber, along with the absorption coefficient measured in the reverberation chamber (see Section 5.4).

Resonance absorbers are very useful in room acoustics as well as in noise control since they offer the possibility to control the reverberation time within limited frequency ranges, in particular at low frequencies.

5.4 Measurement of Sound Absorption

A simple device for measuring the absorption coefficient of a boundary is the impedance tube or Kundt's tube in which a sinusoidal sound wave is excited at one end, whereas the test sample is placed at the other. Both waves, the original one and the wave reflected from the test specimen form a standing wave; the mutual distance of pressure maxima (and also of minima) is $\lambda/2$ (λ = acoustic wavelength).

To determine the absorption coefficient the standing-wave ratio $q = p_{\max}/p_{\min}$ is measured with a movable probe microphone where p_{\max} and p_{\min} are the maximum and minimum pressure amplitude in the standing wave. The absorption coefficient is obtained from

$$\alpha = \frac{4q}{(1+q)^2} \quad (42)$$

Figure 12 Resonance absorber with panel. (a) Construction, the specific mass m_s of the panel is 5 kg/m^2 . (b) Absorption coefficient.

For many practical purposes this information is sufficient. If the specific impedance is to be determined, the phase difference χ between the sound pressures of the incident and the reflected sound wave at the surface of the test specimen is needed. It is obtained from the distance d_{\min} of the first pressure minimum from the specimen:

$$\chi = \pi \left(\frac{4d_{\min}}{\lambda} - 1 \right) \quad (43)$$

From χ and q , the phase angle β and the magnitude of the specific impedance ζ [see Eq. (36)] are calculated using the relations

$$\beta = \text{atn} \left(\frac{q^2 - 1}{2q} \sin \chi \right) \quad (44a)$$

$$|\zeta| = \sqrt{\frac{(q^2 + 1) + (q^2 - 1) \cos \chi}{(q^2 + 1) - (q^2 - 1) \cos \chi}} \quad (44b)$$

For locally absorbing materials the absorption coefficient at random incidence can be determined from these data by using Fig. 9.

As mentioned, the application of the impedance tube is limited to normal sound incidence and to materials for which a small sample can be considered representative for the whole lining. Furthermore, the frequency range is limited by the requirement that the diameter of the tube is smaller than 0.586λ . If the cross section is rectangular, the wider side must be smaller than $\lambda/2$. More details on the construction of the tube and the measuring procedure may be looked up in the relevant international standard.¹⁵

Table 2 Typical Absorption Coefficients of Various Wall Materials (Random Incidence)

Material	Octave Band Center Frequency (Hz)					
	125	250	500	1000	2000	4000
Hard surfaces (concrete, brick walls, plaster, hard floors etc.)	0.02	0.02	0.03	0.04	0.05	0.05
Carpet, 5 mm thick, on solid floor	0.02	0.03	0.05	0.10	0.30	0.50
Slightly vibrating surfaces (suspended ceilings etc.)	0.10	0.07	0.05	0.04	0.04	0.05
Plush curtain, flow resistance 450 N s/m, deeply folded, distance from solid wall ca. 5 cm	0.15	0.45	0.90	0.92	0.92	0.95
Acoustical plaster, 10 mm thick, sprayed on solid wall	0.08	0.15	0.30	0.50	0.60	0.70
Polyurethane foam, 27 kg/m ³ , 15 mm thick on solid wall	0.08	0.22	0.55	0.70	0.85	0.75
Rockwool, 46.5 kg/m ³ , 30 mm thick, on concrete	0.08	0.42	0.82	0.85	0.90	0.88
Same as above, but with 50 mm airspace, laterally partitioned	0.24	0.78	0.98	0.98	0.84	0.86
Metal panels, 0.5 mm thick with 15% perforation, backed by 30 mm rockwool and 30 mm additional airspace, no partitions	0.45	0.70	0.75	0.85	0.80	0.60
Fully occupied audience, upholstered seats	0.50	0.70	0.85	0.95	0.95	0.90

Another important method of absorption measurement is based upon Eq. (30). It is carried out in a so-called reverberation chamber, a room with rigid and smooth walls and with a volume V of 150 to 300 m³. The reverberation time of the chamber is measured both with and without the test sample in it, usually with noise bands of third octave width. The results are T and T_0 . Then the absorption coefficient of the test specimen is

$$\alpha = 0.163 \frac{V}{S'} \left(\frac{1}{T_0} - \frac{S - S'}{S} \frac{1}{T} \right) \quad (45)$$

with S and S' denoting the total wall area and the sample area, respectively.

The reverberation method is well suited for measuring the absorption of almost any type of absorber, wall lining, ceiling and so forth, but also that of single persons, blocks of seats, unoccupied or occupied, and the like. It has the particular advantage that the measurement is carried out under conditions that are typical for many practical application, that is, the procedure yields the absorption at random sound incidence, at least in principle. As the impedance tube method, it is internationally standardized.¹⁶

Special precautions must be taken to provide for a diffuse sound field in a reverberation chamber. This is relatively easy for the empty room, but not so easy if a heavily absorbing test specimen is placed in the room. One way to achieve sound field diffusion is to avoid parallel wall pairs in the design of the measuring chamber. It can be improved by “acoustically rough” walls, the irregularities of which scatter the sound waves. A commonly used alternative is the use of

volume scatterers such as bent shells of plastic or wood that are suspended from the ceiling.

Theoretically, the absorption coefficient determined with this method should agree with α_d from Eq. (35); for a locally reacting boundary it should never exceed 0.951. Instead absorption coefficients in excess of 1 are often observed when highly absorbing materials are examined. Such results that are in contradiction with the very meaning of the absorption coefficient may have several reasons. At first, it should be noted that application of the more correct Eyring formula (31) would yield slightly lower coefficients. A more important source of error is lack of sound field diffusion. Finally, systematic errors may be induced by the so-called edge effect: Sound diffraction at the edges of the test specimen increases its effective area.

Table 2 lists the absorption coefficients of some commonly used materials, wall linings, and the like as measured with the reverberation method.

CHAPTER 5

SOUND PROPAGATION IN THE ATMOSPHERE

Keith Attenborough
Department of Engineering
The University of Hull
Hull, United Kingdom

1 INTRODUCTION

Knowledge of outdoor sound propagation is relevant to the prediction and control of noise from land and air transport and from industrial sources. Many schemes for predicting outdoor sound are empirical and source specific. At present, methods for predicting outdoor noise are undergoing considerable assessment and change in Europe as a result of a recent European Community (EC) Directive and the associated requirements for noise mapping. The attenuation of sound outdoors is the sum of the reductions due to geometric spreading, air absorption, interaction with the ground, barriers, vegetation, and atmospheric refraction. This chapter details the physical principles associated with the sources of attenuation and offers some guidance for assessing their relative importance. More details about the noise reduction caused by barriers, trees, and buildings are to be found in Chapter 122.

2 SPREADING LOSSES

Distance alone will result in wavefront spreading. In the simplest case of a sound source radiating equally in all directions, the intensity I (W m^{-2}) at a distance r (m) from the source of power W (W) is given by

$$I = \frac{W}{4\pi r^2} \quad (1)$$

This represents the power per unit area on a spherical wavefront of radius r . In logarithmic form the relationship between sound pressure level L_p and sound power L_W may be written

$$L_p = L_W - 20 \log r - 11 \text{ dB} \quad (2)$$

From a point sound source, this means a reduction of $20 \log 2$ dB, that is, 6 dB, per distance doubling in all directions. Most sources appear to be point sources when the receiver is at a sufficient distance from them. A point source is omnidirectional. If the source is directional, then (2) is modified by inclusion of the directivity index (DI).

$$L_p = L_W + \text{DI} - 20 \log r - 11 \text{ dB} \quad (3)$$

The directivity index is $10 \log \text{DF}$ dB where DF is the directivity factor, which is the ratio of the actual intensity in a given direction to the intensity of an omnidirectional source of the same power output. Such directivity is either inherent or location induced.

A simple case of location-induced directivity arises if the point source, which would normally create spherical wavefronts of sound, is placed on a perfectly reflecting flat plane. Radiation from the source is thereby restricted to a hemisphere. The directivity factor for a point source on a perfectly reflecting plane is 2 and the directivity index is 3 dB. For a point source at the junction of a vertical perfectly reflecting wall with a horizontal perfectly reflecting plane, the directivity factor is 4 and the directivity index is 6 dB. It should be noted that these adjustments ignore phase effects and assume incoherent reflection.¹

From an infinite line source, the wavefronts are cylindrical; so wavefront spreading means a reduction of 3 dB per distance doubling. Traffic noise may be modeled by a line of incoherent point sources on an acoustically hard surface. If a line source of length l consists of contiguous omnidirectional incoherent elements of length dx and source strength $W dx$, the intensity at a location halfway along the line and at a perpendicular distance d from it, so that $dx = rd\theta/\cos\theta$ where r is the distance from any element at angle θ from the perpendicular, is given by

$$I = \int_{-l/2}^{l/2} \frac{W}{2\pi r^2} dx = \frac{W}{2\pi d} \left[2 \tan^{-1} \left(\frac{l}{2d} \right) \right]$$

This results in

$$L_p = L_W - 10 \log d - 8 + 10 \log \left[2 \tan^{-1} \left(\frac{l}{2d} \right) \right] \text{ dB} \quad (4)$$

Figure 1 shows that attenuation due to wavefront spreading from the finite line source behaves as that from an infinite line at distances much less than the length of the source and as that from a point source at distances greater than the length of the source.

3 ATTENUATION OF OUTDOOR SOUND BY ATMOSPHERIC ABSORPTION

A proportion of sound energy is converted to heat as it travels through the air. There are heat conduction losses, shear viscosity losses, and molecular relaxation losses.² The resulting air absorption becomes significant at high frequencies and at long range, so air acts as a low-pass filter at long range. For a plane wave, pressure P at distance x from a position where the pressure is P_0 is given by

$$P = P_0 e^{-\alpha x/2} \quad (5)$$

Figure 1 Comparison of attenuation due to geometrical spreading from point, infinite line, and finite line sources.

The attenuation coefficient α for air absorption depends on frequency, humidity, temperature, and pressure and may be calculated using Eqs. (6) to (8).³

$$\alpha = f^2 \left[\left(\frac{1.84 \times 10^{-11}}{\left(\frac{T_0}{T} \right)^{1/2} \frac{p_s}{p_0}} \right) + \left(\frac{T_0}{T} \right)^{2.5} \right] \times \left(\frac{0.10680 e^{-3352/T} f_{r,N}}{f^2 + f_{r,N}^2} + \frac{0.01278 e^{-2239.1/T} f_{r,O}}{f^2 + f_{r,O}^2} \right) \frac{\text{nepers}}{\text{m} \cdot \text{atm}} \quad (6)$$

where $f_{r,N}$ and $f_{r,O}$ are relaxation frequencies associated with the vibration of nitrogen and oxygen molecules, respectively, and are given by

$$f_{r,N} = \frac{p_s}{p_0} \left(\frac{T_0}{T} \right)^{1/2} \left(9 + 280 H e^{-4.17[(T_0/T)^{1/3} - 1]} \right) \quad (7)$$

$$f_{r,O} = \frac{p_s}{p_0} \left(24.0 + 4.04 \times 10^4 H \frac{0.02 + H}{0.391 + H} \right) \quad (8)$$

where f is the frequency, T is the absolute temperature of the atmosphere in kelvins, $T_0 = 293.15$ K is the reference value of T (20°C), H is the percentage molar concentration of water vapor in the atmosphere = $\rho_{\text{sat}} r_h p_0 / p_s$, r_h is the relative humidity (%), and p_s is local atmospheric pressure and p_0 is the reference atmospheric pressure (1 atm = 1.01325×10^5 Pa); $\rho_{\text{sat}} = 10^{C_{\text{sat}}}$, where $C_{\text{sat}} = -6.8346(T_0/T)^{1.261} + 4.6151$. These formulas give estimates of the absorption of pure tones to an accuracy of $\pm 10\%$ for $0.05 < H < 5$, $253 < T < 323$, $p_0 < 200$ kPa. It should be noted that use of local meteorological data is necessary when calculating the atmospheric absorption.⁴ Moreover outdoor air absorption varies through the day and the year.⁵

4 DIFFRACTION OVER BARRIERS

Obstacles such as noise barriers that intercept the line of sight between source and receiver and that are large compared to the incident wavelengths reduce the sound at the receiver. As long as the transmission loss through the barrier material is sufficiently high, the performance of a barrier is dictated by the geometry (see Fig. 2).

The total sound field in the vicinity of a semi-infinite half-plane depends on the relative position of source, receiver, and the thin plane. The total sound field p_T in each of three regions shown in Fig. 2 is as follows:

$$\text{In front of the barrier: } p_T = p_i + p_r + p_d \quad (9a)$$

$$\text{Above the barrier: } p_T = p_i + p_d \quad (9b)$$

$$\text{In the shadow zone: } p_T = p_d \quad (9c)$$

Fresnel numbers of the source and image source are denoted, respectively, by N_1 and N_2 are defined as follows:

$$N_1 = \frac{R' - R_1}{\lambda/2} = \frac{k}{\pi} (R' - R_1) \quad (10a)$$

$$N_2 = \frac{R' - R_2}{\lambda/2} = \frac{k}{\pi} (R' - R_2) \quad (10b)$$

where R_1 and R_2 are defined in Fig. 2, $R' = r_s + r_r$ is the shortest path source–edge–receiver, and k the wavenumber corresponding to wavelength λ in air, = $2\pi/\lambda$.

The attenuation (Att dB) of the screen (or sometimes known as the insertion loss, IL, dB) is often used to assess the acoustical performance of the barrier (see also Chapter 122). It is defined as follows:

$$\text{Att} = \text{IL} = 20 \log \left(\left| \frac{p_w}{p_{w/o}} \right| \right) \quad (11)$$

where p_w and $p_{w/o}$ is the total sound field with or without the presence of the barrier.

Maekawa⁶ described the attenuation of a screen using an empirical approach based on the Fresnel number N_1 associated with the source. Hence

$$\text{Att} = 10 \log(3 + 20N_1) \quad (12)$$

Figure 2 Diffraction of sound by a thin barrier.

The Maekawa curve can be represented mathematically by⁷

$$\text{Att} = 5 + 20 \log \frac{\sqrt{2\pi N_1}}{\tanh \sqrt{2\pi N_1}} \quad (13)$$

Menounou⁸ has modified the Kurze–Anderson empirical formula⁷ by using both Fresnel numbers [Eqs. (10)]. The improved Kurze–Anderson formula is given by

$$\text{Att} = \text{Att}_s + \text{Att}_b + \text{Att}_{sb} + \text{Att}_{sp} \quad (14a)$$

where

$$\text{Att}_s = 20 \log \frac{\sqrt{2\pi N_1}}{\tanh \sqrt{2\pi N_1}} - 1 \quad (14b)$$

$$\text{Att}_b = 20 \log \left[1 + \tanh \left(0.6 \log \frac{N_2}{N_1} \right) \right] \quad (14c)$$

$$\text{Att}_{sb} = (6 \tanh \sqrt{N_2} - 2 - \text{Att}_b)(1 - \tanh \sqrt{10N_1}) \quad (14d)$$

$$\text{Att}_{sp} = -10 \log \frac{1}{(R'/R_1)^2 + (R'/R_1)} \quad (14e)$$

The term Att_s is a function of N_1 , which is a measure of the relative position of the receiver from the source. The second term depends on the ratio of N_2/N_1 , which depends on the proximity of either the source or the receiver to the half-plane. The third term is only significant when N_1 is small and depends on the proximity of the receiver to the shadow boundary. The last term, a function of the ratio R'/R_1 , accounts for the diffraction effect due to spherical incident waves.

These formulas only predict the amplitude of sound and do not include wave interference effects. Such interference effects result from the contributions from different diffracted wave paths in the presence of ground.

Consider a source S_g located at the left side of the barrier, a receiver R_g at the right side of the barrier, and O is the diffraction point on the barrier edge (see Fig. 3). The sound reflected from the ground surface can be described by an image of the source, S_i . On the receiver side sound waves will also be reflected from

Figure 3 Diffraction by a barrier on impedance ground.

the ground. This effect can be considered in terms of an image of the receiver, R_i . The pressure at the receiver is the sum of four terms that correspond to the sound paths $S_g E R_g$, $S_i E R_g$, $S_g E R_i$, and $S_i E R_i$.

If the surface is a perfectly reflecting ground, the total sound field is the sum of the diffracted fields of these four paths:

$$P_T = P_1 + P_2 + P_3 + P_4 \quad (15a)$$

where

$$P_1 = P(S_g, R_g, E) \quad P_2 = P(S_i, R_g, E)$$

$$P_3 = P(S_g, R_i, E) \quad P_4 = P(S_i, R_i, E)$$

$P(S, R, E)$ is the diffracted sound field due to a thin barrier for given positions of source S , receiver R , and the point of diffraction at the barrier edge E . If the ground has finite impedance (such as grass or a porous road surface), then the pressure corresponding to rays reflected from these surfaces should be multiplied by the appropriate spherical wave reflection coefficient(s) to allow for the change in phase and amplitude of the wave on reflection as follows:

$$P_r = P_1 + Q_s P_2 + Q_R P_3 + Q_s Q_R P_4 \quad (16)$$

where Q_s and Q_R are the spherical wave reflection coefficients for the source and receiver side, respectively. The spherical wave reflection coefficients can be calculated according to Eq. (27) for different types of ground surfaces and source/receiver geometries.

For a given source and receiver position, the acoustical performance of the barrier on the ground is normally assessed by use of either the excess attenuation (EA) or the insertion loss (IL). They are defined as follows:

$$\text{EA} = \text{SPL}_f - \text{SPL}_b \quad (17)$$

$$\text{IL} = \text{SPL}_g - \text{SPL}_b \quad (18)$$

where SPL_f is the free field noise level, SPL_g is the noise level with the ground present, and SPL_b is the noise level with the barrier and ground present. Note that, in the absence of a reflecting ground, the numerical value of EA (which was called Att previously) is the same as IL. If the calculation is carried out in terms of amplitude only, then the attenuation Att_n for each sound path can be directly determined from the appropriate Fresnel number F_n for that path. The excess attenuation of the barrier on a rigid ground is then given by

$$A_T = 10 \log \left(10^{-\left| \frac{\text{Att}_1}{10} \right|} + 10^{-\left| \frac{\text{Att}_2}{10} \right|} + 10^{-\left| \frac{\text{Att}_3}{10} \right|} + 10^{-\left| \frac{\text{Att}_4}{10} \right|} \right) \quad (19)$$

The attenuation for each path can either be calculated by empirical or analytical formulas depending on the complexity of the model and the required accuracy. Lam and Roberts⁹ have suggested a simple approach capable of modeling wave effects in which the phase of the wave at the receiver is calculated from the path length, r_r , via the top of the screen, assuming a $\pi/4$ phase change in the diffracted wave. This phase change is assumed to be constant for all source–barrier–receiver geometries. For example, the diffracted wave along the path $S_g ER_g$ would be given by

$$P_1 = \text{Att}_1 e^{i[k(r_0+r_r)+\pi/4]} \quad (20)$$

This approach provides a reasonable approximation for the many situations of interest where source and receiver are many wavelengths from the barrier and the receiver is in the shadow zone.

5 ATTENUATION CAUSED BY FINITE BARRIERS AND BUILDINGS

All noise barriers have finite length and, for certain conditions, sound diffracting around the vertical ends of the barrier may be significant. This will be the case for sound diffracting around buildings also. Figure 4 shows the eight diffracted ray paths contributing to the total field behind a finite-length barrier situated on finite impedance ground. In addition to the four “normal” ray paths diffracted at the top edge of the barrier (see Fig. 3), four more ray paths are diffracted at the vertical edges, that is, two rays at either edge being, respectively, the direct diffracted ray and the diffracted-and-reflected ray.

The reflection angles of the two diffracted-and-reflected rays are independent of the barrier position. Rays reflect either at the source side or on the receiver side of the barrier, depending on the relative positions of the source, receiver, and barrier. The total field is given by

$$P_T = P_1 + Q_s P_2 + Q_R P_3 + Q_s Q_R P_4 + P_5 \\ + Q_R P_6 + P_7 + Q_R P_8 \quad (21)$$

Figure 4 Ray paths around a finite length barrier or building on the ground.

where P_1 to P_4 are those given earlier for the diffraction at the top edge of the barrier.

Although accurate diffraction formulas may be used to compute P_i ($i = 1, \dots, 8$), a simpler approach is to assume that each diffracted ray has a constant phase shift of $\pi/4$ regardless the position of source, receiver, and diffraction point. Further detail on barrier attenuation will be found in Chapter 122.

6 GROUND EFFECTS

Ground effects (for elevated source and receiver) are the result of interference between sound traveling directly from source to receiver and sound reflected from the ground when both source and receiver are close to the ground. Sometimes the phenomenon is called ground absorption but, since the interaction of outdoor sound with the ground involves interference, there can be enhancement as well as attenuation. Above ground, such as nonporous concrete or asphalt, the sound pressure is doubled more or less over a wide range of audible frequencies. Such ground surfaces are described as *acoustically hard*. Over porous surfaces, such as soil, sand, and snow, enhancement tends to occur at low frequencies since the larger the sound wave the less able it is to penetrate the pores. The presence of vegetation tends to make the surface layer of ground including the root zone more porous. The layer of partly decayed matter on the floor of a forest is highly porous. Snow is significantly more porous than soil and sand. Porous ground surfaces are sometimes called *acoustically soft* or may be referred to as *finite impedance* ground surfaces.

7 BOUNDARY CONDITIONS AT THE GROUND

Typically, the speed of sound in the ground is much slower than that in the air, that is, $c \gg c_1$. The propagation of sound in the air gaps between solid particles is impeded by viscous friction. This in turn means that the index of refraction in the ground, $n_1 = c/c_1 \gg 1$, and any incoming sound ray is refracted toward the normal as it propagates from air and penetrates the ground. This type of ground surface is called *locally reacting* because the air–ground interaction is independent of the angle of incidence of the incoming waves. The acoustical properties of locally reacting ground may be represented simply by its relative normal incidence surface impedance (Z), or its inverse (the relative admittance β), and the ground is said to form an impedance boundary. A perfectly hard ground has infinite impedance (zero admittance). A perfectly soft ground has zero impedance (infinite admittance). If the ground is not locally reacting, that is, it is externally reacting, then there are two separate boundary conditions governing the continuity of pressure and the continuity of the normal component of air particle velocity.

8 ATTENUATION OF SPHERICAL ACOUSTIC WAVES OVER THE GROUND

The idealized case of a point (omnidirectional) source of sound at height z_s and a receiver at height z and

Figure 5 Sound propagation from a point source to a receiver above a ground surface.

horizontal distance r above a finite impedance plane (admittance β) is shown in Fig. 5.

Between source and receiver there is a direct sound path of length R_1 and a ground-reflected path of length R_2 . With the restrictions of long range ($r \approx R_2$), high frequency [$kr \gg 1$, $k(z + z_s) \gg 1$], where $k = \omega/c$ and $\omega = 2\pi f$ (f being frequency) and with both the source and receiver located close ($r \gg z + z_s$) to a relatively hard ground surface ($|\beta|^2 \ll 1$), the total sound field at (x, y, z) can be determined from

$$p(x, y, z) = \frac{e^{ikR_1}}{4\pi R_1} + \frac{e^{ikR_2}}{4\pi R_2} + \Phi_p + \Phi_s \quad (22)$$

where

$$\Phi_p \approx 2i\sqrt{\pi} \left(\frac{1}{2}kR_2\right)^{1/2} \beta e^{-w^2} \text{erfc}(-iw) \frac{e^{ikR_2}}{4\pi R_2} \quad (23)$$

and w , sometimes called the numerical distance, is given by

$$w \approx \frac{1}{2}(1+i)\sqrt{kR_2}(\cos\theta + \beta) \quad (24)$$

In (22), Φ_s represents a surface wave and is small compared with Φ_p under most circumstances. It is included in careful computations of the complementary error function [$\text{erfc}(x)$].^{10,11}

After rearrangement, the sound field due to a point monopole source above a locally reacting ground becomes

$$p(x, y, z) = \frac{e^{ikR_1}}{4\pi R_1} + [R_p + (1 - R_p)F(w)] \frac{e^{ikR_2}}{4\pi R_2} \quad (25)$$

where R_p is the plane wave reflection coefficient and $F(w)$, sometimes called the boundary loss factor, is given by

$$F(w) = 1 + i\sqrt{\pi}w \exp(-w^2) \text{erfc}(-iw) \quad (26)$$

where $F(w)$ results from the interaction of a spherical wavefront with a ground of finite impedance. The term in the square bracket of (25) may be interpreted as the spherical wave reflection coefficient:

$$Q = R_p + (1 - R_p)F(w) \quad (27)$$

If the plane wave reflection coefficient is used in (25) instead of the spherical wave reflection coefficient, it leads to the prediction of zero sound pressure when both source and receiver are on the ground ($R_p = -1$ and $R_1 = R_2$). The contribution of the second term of Q to the total field allows for the fact that the wavefronts are spherical rather than plane and has been called the *ground wave*, in analogy with the corresponding term in the theory of AM radio reception.¹² If the wavefront is plane ($R_2 \rightarrow \infty$), then $|w| \rightarrow \infty$ and $F \rightarrow 0$. If the surface is acoustically hard, then $|\beta| \rightarrow 0$, which implies $|w| \rightarrow 0$ and $F \rightarrow 1$. If $\beta = 0$, the sound field consists of two terms: a direct wave contribution and a specularly reflected wave from the image source, and the total sound field may be written

$$p(x, y, z) = \frac{e^{ikR_1}}{4\pi R_1} + \frac{e^{ikR_2}}{4\pi R_2}$$

This has a first minimum corresponding to destructive interference between the direct and ground-reflected components when $k(R_2 - R_1) = \pi$, or $f = c/2(R_2 - R_1)$. Normally this destructive interference is at too high a frequency to be of importance in outdoor sound prediction. The higher the frequency of the first minimum in the ground effect, the more likely that it will be destroyed by turbulence.

For $|\beta| \ll 1$ but at grazing incidence ($\theta = \pi/2$), so that $R_p = -1$ and

$$p(x, y, z) = 2F(w)e^{ikr}/r \quad (28)$$

The numerical distance, w , is given by

$$w = \frac{1}{2}(1+i)\beta\sqrt{kr} \quad (29)$$

Equation (25) is the most widely used analytical solution for predicting the sound field above a locally reacting ground in a homogeneous atmosphere. There are many other accurate asymptotic and numerical solutions available but no significant numerical differences between various predictions have been revealed for practical geometries and typical outdoor ground surfaces.

Although it is numerically part of the calculation of the complementary error function, the surface wave is a separate contribution propagating close to and parallel to the porous ground surface. It produces elliptical motion of air particles as the result of combining motion parallel to the surface with that normal to the surface in and out of the pores. The surface wave decays with the inverse square root of range rather than inversely with range as is true for other components. At grazing incidence on a plane with high impedance such that $|\beta| \rightarrow 0$, the condition for the existence of a surface wave is simply that the imaginary part of the ground impedance (the reactance) is greater than the real part (the resistance). Surface waves due to a point source have been generated and studied extensively in laboratory experiments over

cellular or lattice surfaces placed on smooth hard surfaces.¹³⁻¹⁶ The outdoor ground type that most likely produce measurable surface waves is a thin layer of snow over a frozen ground, and such waves over snow have been observed using blank pistol shots.¹⁷

There are some cases where it is not possible to model the ground surface as an impedance plane, that is, n_1 is not sufficiently high to warrant the assumption that $n_1 \gg 1$. In this case, the refraction of sound wave depends on the angle of incidence as sound enters into the porous medium. This means that the apparent impedance depends not only on the physical properties of the ground surface but also, critically, on the angle of incidence. It is possible to introduce an *effective* admittance, β_e , defined by

$$\beta_e = \zeta_1 \sqrt{n_1^2 - \sin^2 \theta} \quad (30)$$

where ζ_1 is the density ratio of air to ground, $\zeta_1 = \rho/\rho_1 \ll 1$. This allows use of the same results as before but with admittance replaced by the effective admittance (30) for a semi-infinite nonlocally reacting ground.¹⁸ There are some situations where there is a highly porous surface layer above a relatively nonporous substrate. This is the case with forest floors consisting of partly decomposed litter layers above relatively high flow resistivity soil, with freshly fallen snow on a hard ground or with porous asphalt laid on a nonporous substrate. The minimum depth, d_m , for such a multiple layer ground to be treated as a semi-infinite externally reacting ground to satisfy the above condition depends on the acoustical properties of the ground and the angle of incidence, but we can consider two limiting cases. Denoting the complex wavenumber or propagation constant within the surface layer of the ground by $k_1 = k_r + ik_x$, and for normal incidence, where $\theta = 0$, the required condition is simply

$$d_m > 6/k_x \quad (31)$$

For grazing incidence where $\theta = \pi/2$, the required condition is

$$d_m > 6 \left[\sqrt{\frac{(k_r^2 - k_x^2 - 1)^2}{4} + k_r^2 k_x^2} - \frac{k_r^2 - k_x^2 - 1}{2} \right]^{1/2} \quad (32)$$

It is possible to derive an expression for the effective admittance of a ground with an arbitrary number of layers. However, sound waves can seldom penetrate more than a few centimetres in most outdoor ground surfaces. Lower layers contribute little to the total sound field above the ground and, normally, consideration of ground structures consisting of more than two layers is not required for predicting outdoor sound. Nevertheless, the assumption of a double layer structure¹⁸ has been found to enable improved agreement with data obtained over snow.¹⁹ It has been shown that, in cases where the surface

impedance depends on angle, replacing the normal surface impedance by the grazing incidence value is sufficiently accurate for predicting outdoor sound.²⁰

9 ACOUSTIC IMPEDANCE OF GROUND SURFACES

For most outdoor sound predictions, the ground may be considered to be a porous material with a rigid, rather than elastic, frame. The most important characteristic of a ground surface that affects its acoustical character is its flow resistivity or air permeability. Flow resistivity is a measure of the ease with which air can move in and out of the ground. It represents the ratio of the applied pressure gradient to the induced volume flow rate per unit thickness of material and has units of Pa s m^{-2} . If the ground surface has a high flow resistivity, it means that it is difficult for air to flow through the surface. Flow resistivity increases as porosity decreases. For example, conventional hot-rolled asphalt has a very high flow resistivity (10 million Pa s m^{-2}) and negligible porosity, whereas drainage asphalt has a volume porosity of up to 0.25 and a relatively low flow resistivity ($< 30,000 \text{ Pa s m}^{-2}$). Soils have volume porosities of between 10 and 40%. A wet compacted silt may have a porosity that can be as low as 0.1 and a rather high flow resistivity (4 million Pa s m^{-2}). Newly fallen snow has a porosity of around 60% and a fairly low flow resistivity ($< 10,000 \text{ Pa s m}^{-2}$). The thickness of the surface porous layer also is important and whether or not it has acoustically hard substrate.

A widely used model for the acoustical properties of outdoor surfaces involves a single parameter, the "effective" flow resistivity, σ_e , to characterize the ground.²¹ According to this single-parameter model, the propagation constant, k , and normalized characteristic impedance, Z , are given by

$$\frac{k}{k_1} = \left[1 + 0.0978 \left(\frac{f}{\sigma_e} \right)^{-0.700} + i0.189 \left(\frac{f}{\sigma_e} \right)^{-0.595} \right] \quad (33a)$$

$$Z = \frac{\rho_1 c_1}{\rho c} = 1 + 0.0571 \left(\frac{f}{\sigma_e} \right)^{-0.754} + i0.087 \left(\frac{f}{\sigma_e} \right)^{-0.732} \quad (33b)$$

This model may be used for a locally reacting ground as well as for an extended reaction surface. On occasion, better agreement with grassland data²² has been obtained by assuming that the ground surface is that of a hard-backed porous layer of thickness d such that the surface impedance Z_s is given by

$$Z_s = Z \coth(-ikd) \quad (34)$$

A model based on an exponential change in porosity with depth has been suggested.^{23,24} Although this model is suitable only for a high flow resistivity (i.e., locally reacting) ground, for many outdoor ground surfaces, it has enabled better agreement with measured data than obtained using Eq. (33b). The two adjustable parameters are the effective flow resistivity (σ_e) and the effective rate of change of porosity with depth (α_e). The impedance of the ground surface is predicted by

$$Z = 0.436(1 + i) \sqrt{\frac{\sigma_e}{f}} + 19.74i \frac{\alpha_e}{f} \quad (35)$$

More sophisticated analytical models for the acoustical properties of rigid-porous materials introduce porosity, the tortuosity (or “twistiness”) of the pores, factors related to pore shape,²⁵ and multiple layering. Models that introduce the viscous and thermal characteristic dimensions of pores²⁶ are based on a formulation by Johnson et al.²⁷ Recently, it has been shown possible to obtain explicit relationships between the characteristic dimensions and grain size by assuming a specific microstructure of identical stacked spheres.²⁸ Other developments allow for a log-normal pore size distribution, while assuming pores of identical shape.^{29–30} On occasion it is important to include multiple layering also. A standard method for obtaining ground impedance is the template method based on short-range measurements of excess attenuation.³¹ It should be noted that parameters deduced from data according to (33) to (35) show that there can be a wide range of parameter values for “grassland”.

10 EFFECTS OF SMALL-SCALE ROUGHNESS

There have been advances also in methods of obtaining surface admittance directly.³² Measurements obtained over uncultivated grassland,³³ using this direct impedance-fitting method, indicate that the surface impedance tends to zero above 3 kHz. Reflection involving incoherent scatter from a randomly rough porous surface may be used to explain these measurements. The assumed flow resistivity and porosity are within the expected range for a soil. However, small-scale roughness must be included to provide a reasonable fit to these grassland data. For grazing incidence on a hard surface containing randomly distributed two-dimensional (2D) roughness normal to the roughness axes, the effective admittance may be written³⁴

$$\beta = \left(\frac{3V^2 k^3 b}{2} \right) \left(1 + \frac{\delta^2}{2} \right) - iVk(\delta - 1) \quad (36)$$

where V is the roughness volume per unit area of surface (equivalent to mean roughness height), b is the mean center-to-center spacing, δ is an interaction factor depending on the “shape” and “concentration” of the roughness and, as before, k is the wavenumber in air. An interesting consequence of (36) is that a surface that would be acoustically hard if smooth has, effectively, a finite impedance when rough. The real part

of the admittance allows for incoherent scatter from the surface and varies with the cube of frequency and the square of the roughness volume per unit area. The same approach can be extended to give the effective normalized surface admittance of a porous surface containing 2D roughness.^{33,35} It is possible to obtain the following approximation for the impedance of a randomly rough porous surface near grazing incidence³⁶:

$$Z_r \approx Z_s - \left(\frac{\langle H \rangle R_s}{\gamma \rho_0 c_0} \right) \left(\frac{2}{v} - 1 \right) \quad [\text{Re}(Z_r) \geq 0] \quad (37)$$

where $v = 1 + \frac{2}{3}\pi \langle H \rangle$ and $\langle H \rangle$ is the root-mean-square roughness height.

Cultivation practices intended to break up soil compaction beneath the ground surface caused, for example, by repeated passage of heavy vehicles, have important influences on ground effect since they change the surface properties. Aylor³⁷ noted a significant change in the excess attenuation at a range of 50 m over a soil after disking without any noticeable change in the meteorological conditions. Plowing turns the soil surface over to a depth of about 0.15 m. Measurements taken over cultivated surfaces before and after subsoiling and plowing have been shown to be consistent with predicted effects of the resulting changes in surface roughness and flow resistivity.³⁸

11 EXAMPLES OF GROUND ATTENUATION UNDER WEAKLY REFRACTING CONDITIONS

Pioneering studies of the combined influences of the ground surface and meteorological conditions were carried out using a fixed Rolls Royce Avon jet engine as a source (nozzle-center height 1.82 m) at two grass-covered airfields (Radlett and Hatfield).^{39,40} Examples of the resulting data, quoted as the difference between sound pressure levels registered by microphones at 1.5 m height and horizontal distances of 19 m (the reference location) and 347 m, corrected for the decrease expected from spherical spreading and air absorption, are shown in Fig. 6.

The data over grass cover were obtained with a positive vector wind (from source to receiver) of 1.27 m/s (5 ft/s). The ground attenuation at Hatfield, although still a major propagation factor, that is, over 15 dB near 400 Hz, was less than that at Radlett, and its maximum value occurred at a higher frequency. Snowfall during the period of these measurements also enabled study of the influence of several centimetres of snow with a comparable positive vector wind of 1.52 m/s (6 ft/s). These data revealed the large effect at low frequencies, that is, over 20 dB attenuation in the 63- and 125-Hz third-octave bands, over snow.

Noise measurements have been made to distances of 3 km during aircraft engine runups with the aim of defining noise contours in the vicinity of airports.⁴¹ Measurements were made for a range of power settings during several summer days under near to calm weather conditions (wind speed < 5 m/s, temperature between 20 and 25°C). Between 7 and 10 measurements were made at every measurement station

Figure 6 Data for the level difference between microphones at 19 and 347 m from a fixed jet engine source with a positive vector wind between source and receiver of 1.27 m/s (5 ft/s) corrected for wavefront spreading and air absorption. \square represent data at Radlett; \diamond represent data at Hatfield; \times represent data obtained over approximately 0.15 m thick (6–9 in.) snow at Hatfield.

(in accordance with ICAO Annex 16 requirements) and the results have been averaged. Example results are shown in Fig. 7. It can be shown that these data are consistent with nearly acoustically neutral conditions.⁴¹ Note that at 3 km, the measured levels are more than 30 dB less than would be expected from wavefront spreading and air absorption only.

At distances of less than between 500 and 700 m from the engine, the data suggest attenuation rates near to the “concrete” or “spherical spreading plus air absorption” predictions. Beyond 700 m the measured

Figure 7 Measured differences between the A-weighted sound pressure level at 100 m and those measured at ranges up to 3 km during an Il-86 aircraft’s engine test in the direction of the maximum jet noise generation ($\sim 40^\circ$ from exhaust axis) and predictions for levels due to a point source at the engine center height assuming spherical spreading plus air absorption and various types of ground.

attenuation rate is nearer to the “soil” or between the “soil” and “grass” predictions. This is the result of the fact that the runups took place over the concrete surface of an apron and further away (i.e., between 500 and 700 m in various directions) the ground surface was “soil” and/or “grass.”

12 ATTENUATION THROUGH TREES AND FOLIAGE

Ignoring meteorological effects, a mature forest or woodland may have three types of influence on sound. First is ground effect. This is particularly significant if there is a thick litter layer of partially decomposing vegetation on the forest floor. In such a situation the ground surface consists of a thick highly porous layer with rather low flow resistivity thus giving a primary excess attenuation maximum at lower frequencies than observed over typical grassland. This is consistent with the data collected over ranges of 500 m⁴² and is similar to the effect, mentioned earlier, over snow. Second, the trunks and branches scatter the sound out of the path between source and receiver. Third, the foliage attenuates the sound by viscous friction.

Predictions of the total attenuation through woodland, in qualitative agreement with measurements made during conditions with little or no wind and small temperature gradients, have been obtained by adding the contributions to attenuation for large cylinders (representing trunks), small cylinders (representing foliage), and the ground.⁴³ But it is necessary to adjust several parameters to obtain quantitative agreement. Foliage has the greatest effect above 1 kHz and the foliage attenuation increases approximately in a linear fashion with frequency. Figure 8 shows a typical variation of attenuation with frequency and linear fits to the foliage attenuation.

13 WIND AND TEMPERATURE GRADIENT EFFECTS ON OUTDOOR SOUND PROPAGATION

The atmosphere is constantly in motion as a consequence of wind shear and uneven heating of Earth’s surface (Fig. 9). Any turbulent flow of a fluid across a rough solid surface generates a boundary layer. Most interest, from the point of view of outdoor sound prediction, focuses on the lower part of the meteorological boundary layer called the surface layer. In the surface layer, turbulent fluxes vary by less than 10% of their magnitude, but the wind speed and temperature gradients are largest. In typical daytime conditions the surface layer extends over 50 to 100 m. Usually it is thinner at night. Turbulence may be modeled in terms of a series of moving eddies or “turbules” with a distribution of sizes.

In most meteorological conditions, the speed of sound changes with height above the ground. Usually, temperature decreases with height (the adiabatic lapse condition). In the absence of wind, this causes sound waves to bend, or refract, upward. Wind speed adds or subtracts from sound speed.

When the source is downwind of the receiver the sound has to propagate upwind. As height increases,

Figure 8 (Left) Measured attenuation through alternate bands of Norway spruce and oak (planted in 1946) with Hawthorn, roses, and honeysuckle undergrowth; visibility less than 24 m. (Right) Linear fits to attenuation above 1 kHz in mixed conifers (squares), mixed deciduous summer (circles), and spruce monoculture (diamonds). Also shown is the foliage attenuation predicted according to ISO 9613-2.

the wind speed increases and the amount being subtracted from the speed of sound increases, leading to a negative sound speed gradient. Downwind, sound pressure refracts downward. Wind effects tend to dominate over temperature effects when both are present. Temperature inversions, in which air temperature increases up to the inversion height, cause sound waves to refract downward below that height. Under inversion conditions, or downwind, sound pressure levels decrease less rapidly than would be expected from wavefront spreading alone.

Figure 9 Schematic representation of the daytime atmospheric boundary layer and turbulent eddy structures. The sketch graph on the left shows the mean wind speed (U) and the potential temperature profiles ($\theta = T + \gamma_d z$, where $\gamma_d = -0.098^\circ\text{C/km}$ is the dry adiabatic lapse rate, T is the temperature and z is the height).

In general, the relationship between sound speed profile $c(z)$, temperature profile $T(z)$, and wind speed profile $u(z)$ in the direction of sound propagation is given by

$$c(z) = c(0) \sqrt{\frac{T(z) + 273.15}{273.15}} + u(z) \quad (38)$$

where T is in degrees Celsius and u is in metres/second.

14 SHADOW ZONES

A negative sound gradient means upward refraction and the creation of a sound shadow at a distance from the source that depends on the gradient. The presence of a shadow zone means that the sound pressure level decreases faster than would be expected from distance alone. A combination of slightly negative temperature gradient, strong upwind propagation, and air absorption has been observed, in carefully monitored experiments, to reduce sound pressure levels, 640 m from a 6-m-high source over relatively hard ground, by up to 20 dB more than expected from spherical spreading.⁴⁴ Since shadow zones can be areas in which there is significant excess attenuation, it is important to determine their boundaries.

For a source close to the ground, assuming circular ray paths, the distance to the shadow zone is given approximately by

$$x = \left[2c_0 / \left(-\frac{dc}{dz} \right) \right]^{1/2} (\sqrt{h_s} + \sqrt{h_r}) \quad (39)$$

where h_s and h_r are heights of source and receiver, respectively, and dc/dz must be negative for a temperature-induced shadow zone.

When a wind is present, the combined effects of temperature lapse and wind will tend to enhance the shadow zone upwind of the source, since wind speed tends to increase with height. Downwind of the source, however, the wind will counteract the effect of temperature lapse, and the shadow zone will be destroyed. In any case, an acoustic shadow zone is never as complete as an optical one would be, as a result of diffraction and turbulence. In the presence of wind with a wind speed gradient of du/dz , the formula for the distance to the shadow zone boundary is given by

$$x = \left[2c_0 \left/ \frac{du}{dz} \cos \beta - \frac{dc}{dz} \right. \right]^{1/2} (\sqrt{h_s} + \sqrt{h_r}) \quad (40)$$

where β is the angle between the direction of the wind and the line between source and receiver.

Note that there will be a value of the angle β , (say β_c), given by

$$\frac{du}{dz} \cos \beta_c = \frac{dc}{dz}$$

or

$$\beta_c = \cos^{-1} \left(\frac{dc}{dz} \left/ \frac{du}{dz} \right. \right) \quad (41)$$

at and beyond which there will not be a shadow zone. This represents the critical angle at which the effect of wind counteracts that of the temperature gradient.

15 ATMOSPHERIC TURBULENCE

Shadow zones due to atmospheric refraction are penetrated by sound scattered by turbulence, and this sets a limit of the order of 20 to 25 dB to the reduction of sound pressure levels within the sound shadow.^{45,46} Another consequence of atmospheric turbulence is a fluctuation of the amplitude of outdoor sound at any given receiver. The extent of this fluctuation caused by turbulence initially increases with increasing distance of propagation, sound frequency, and strength of turbulence but reaches a limiting value fairly quickly. This means that the fluctuation in overall sound pressure levels from distant sources (e.g., line-of-sight from an aircraft at a few kilometres) may have a standard deviation of no more than about 6 dB.⁴⁶

Turbulence destroys the coherence between direct and ground-reflected sound and consequently reduces the destructive interference in ground effect. Equation (25) may be modified to obtain the mean-squared pressure at a receiver in a turbulent but *acoustically neutral* (no refraction) atmosphere⁴⁷

$$\langle p^2 \rangle = \frac{1}{R_1^2} + \frac{|Q|^2}{R_2^2} + \frac{2|Q|}{R_1 R_2} \cos[k(R_2 - R_1) + \theta] C \quad (42)$$

where θ is the phase of the reflection coefficient, ($Q = |Q|e^{i\theta}$), C is the coherence factor determined

by the turbulence effect, R_1 is the direct sound path length, and R_2 is the ground-reflected path length.

Hence the sound pressure level, P , is given by

$$P = 10 \log_{10}(\langle p^2 \rangle) \quad (43)$$

Most recent calculations of turbulence effects on outdoor sound have relied on estimated or best-fit values, rather than measured values, of turbulence parameters. Although assumption of a Gaussian spectrum provides a poor overall description of the spectrum of atmospheric turbulence, it allows many results to be obtained in simple analytical form.⁴⁸ Typically, the high wavenumber part of the spectrum is the main contributor to turbulence effects on sound propagation. So the assumption of a Gaussian spectrum results in best-fit parameter values that are rather less than those that are measured. For a Gaussian turbulence spectrum, the coherence factor, C , is given by⁴⁹

$$C = e^{-\sigma^2(1-\rho)} \quad (44)$$

where σ^2 is the variance of the phase fluctuation along a path and ρ is the phase covariance between adjacent paths (e.g., direct and reflected).

$$\sigma^2 = A \sqrt{\pi} \langle \mu^2 \rangle k^2 R L_0 \quad (45)$$

of the index of refraction, and L_0 is the outer (inertial) scale of turbulence.

The coefficient A is given by

$$A = 0.5 \quad R > k L_0^2 \quad (46a)$$

$$A = 1.0 \quad R < k L_0^2 \quad (46b)$$

The parameters $\langle \mu^2 \rangle$ and L_0 may be determined from field measurements or estimated.

The phase covariance is given by

$$\rho = \frac{\sqrt{\pi}}{2} \frac{L_0}{h} \operatorname{erf} \left(\frac{h}{L_0} \right) \quad (47)$$

where h is the maximum transverse path separation and $\operatorname{erf}(x)$ is the error function defined by

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \quad (48)$$

For a sound field consisting *only* of direct and reflected paths (which will be true at short ranges) in the absence of refraction, the parameter h is the mean propagation height given by

$$\frac{1}{h} = \frac{1}{2} \left(\frac{1}{h_s} + \frac{1}{h_r} \right) \quad (49)$$

where h_s and h_r are the source and receiver heights, respectively. Daigle⁴⁹ uses half this value to obtain better agreement with data.

Near grazing incidence, if $h \rightarrow 0$, then $\rho \rightarrow 1$ and $C \rightarrow 1$. For greatly elevated source and/or receiver, $h \rightarrow$ large and $C \rightarrow$ maximum. The mean-squared refractive index may be calculated from the measured instantaneous variation of wind speed and temperature with time at the receiver. Specifically

$$\langle \mu^2 \rangle = \frac{\sigma_w^2 \cos^2 \alpha}{C_0^2} + \frac{\sigma_T^2}{4T_0^2}$$

where σ_w^2 is the variance of the wind velocity, σ_T^2 is the variance of the temperature fluctuations, α is the wind vector direction, and C_0 and T_0 are the ambient sound speed and temperature, respectively. Typical values of best-fit mean-squared refractive index are between 10^{-6} for calm conditions and 10^{-4} for strong turbulence. A typical value of L_0 is 1 m but in general a value equal to the source height should be used.

16 CONCLUDING REMARKS

During the last few years there have been considerable advances in numerical and analytical methods for outdoor sound prediction.^{50,51} Details of these are beyond the scope of this work, but a review of recent progress may be found in Berengier et al.⁵² As mentioned in the introduction, methods for predicting outdoor noise are undergoing considerable assessment and change in Europe as a result of a recent EC Directive⁵³ and the associated requirements for noise mapping. At the time of this writing, a European project HARMONOISE⁵⁴ is developing a comprehensive source-independent scheme for outdoor sound prediction. As in NORD2000,⁵⁵ various relatively simple formulas predicting the effect of topography, for example, are being derived and tested against numerical predictions.

CHAPTER 6

SOUND RADIATION FROM STRUCTURES AND THEIR RESPONSE TO SOUND

Jean-Louis Guyader

Vibration and Acoustics Laboratory
National Institute of Applied Sciences of Lyon
Villeurbanne, France

1 INTRODUCTION

Sound radiation from structures and their response to sound can be seen as the interaction of two subsystems: the structure and the acoustic medium, both being excited by sources, mechanical for the structure and acoustical in the fluid¹⁻⁴. The interaction is generally separated into two parts: (1) the radiation describing the transmission from the structure to the acoustic medium and (2) the fluid loading that takes into account the effect of the fluid on the structure. The resolution of the problem in general is difficult, and it is preferable, in order to predict and understand the underlying phenomena, to study separately 1) acoustic radiation from structures and 2) structural excitation by sound. Even with the separation into two problems, simple explanations of the phenomena are difficult to make, and for the sake of simplicity the case of plane structures is used as a reference.

1.1 Chapter Contents

The chapter begins with an explanation of radiation from simple sources, monopoles and dipoles, and a discussion on indicators like radiation factors used in more complicated cases. The generalization to multipolar sources is then presented which leads to the concept of equivalent sources to predict radiation from structures. In Section 2 wave analysis of radiation from planar sources is presented and this permits the separation of structural waves into radiating and nonradiating components; this approach explains why the reduction of vibration does not introduce in general an equivalent decrease of noise radiated.

The integral equation to predict radiation from structures is presented in Section 3. The application to finite, baffled plates is described using modal expansion for the plate response. For modal frequencies below the critical frequency, the radiation is poor because of acoustical short circuiting. Physically, only the edges or corners of the plate are responsible for noise emission. Finally the excitation of structures by sound waves is studied. The presence of acoustic media produces added mass and additional damping on structures. For heavy fluids, the effect is considerable. With light fluids only slight modifications of modal mass and modal damping are observed.

The plate excitation by propagating acoustic waves depends on the acoustic and mechanical wavelengths; for infinite plates the phenomenon of coincidence is described, which appears also in finite plates when resonant modes with maximum joint acceptance are excited.

2 ELEMENTARY SOURCES OF SOUND RADIATION

Acoustic fields associated with elementary sources are of great interest 1) because they characterize some basic behaviors of radiating bodies; for example, one can introduce easily the concepts of radiation efficiency and directivity, and 2) because they can be used to express the radiation of complicated objects. The method to predict the radiated pressure of vibrating surfaces with multipole decomposition (or equivalent source decomposition) is briefly presented here. A second method that constitutes the standard calculation of the radiated field is the integral representation of the pressure field. In this method two elementary sources are of basic importance: the monopole and the dipole. This importance is due to the possibility of representing all acoustic sources associated with structural vibration by a layer of monopoles and a layer of dipoles. This approach is presented in Section 3.

2.1 Sound Radiated by a Pulsating Sphere: Monopole

The sound radiated by a pulsating sphere of radius a , centered at point M_0 , and having a radial surface velocity V is a spherical wave having the well-known expression :

$$p(M, M_0) = V \rho_0 c \frac{jka^2}{1 + jka} \exp(jka) \frac{\exp(-jkr)}{r} \quad (1)$$

where $r = |MM_0|$ is the distance between points M and M_0 , c is the speed of sound, and ρ_0 is the mass density of the acoustic medium. The expression for the sound pressure radiated is only valid outside the sphere, namely when $r > a$.

The acoustic radiation can be characterized through energy quantities, in particular the sound power radiated and the radiation factor.

The radial velocity V_r and radial sound intensity I_r of the spherical wave are, respectively,

$$V_r = V \frac{ka^2}{1 + jka} \frac{1 + jkr}{kr^2} \exp(jka) \exp(-jkr) \quad (2)$$

$$I_r = V^2 \frac{k^2 a^2}{1 + k^2 a^2} \frac{a^2}{r^2} \rho_0 c \quad (3)$$

The acoustic field radiated by a pulsating sphere is nondirectional. This is, of course, due to the spherical symmetry of the source. The radiated power Π_{rad} can be calculated on the sphere's surface or on a sphere at a distance r , the result being the same and given by

$$\Pi_{\text{rad}} = 4\pi V^2 \frac{k^2 a^2}{1 + k^2 a^2} a^2 \rho_0 c \quad (4)$$

An important parameter to describe the radiation from the vibrating object is the radiation factor σ . It is defined as the ratio of the sound power radiated to the square of the velocity of the source times the acoustic impedance $\rho_0 c$. It is nondimensional and indicates the radiation efficiency of the vibration field. In the present case one has

$$\sigma = \frac{k^2 a^2}{1 + k^2 a^2} \quad (5)$$

The radiation efficiency of a pulsating sphere depends on the nondimensional frequency ka . For small values of ka , the efficiency is low and tends to unity when ka increases. This means also that, at a given frequency, a large sphere is a better radiator than a small one. This tendency is true in general; a small object is not an efficient radiator of noise at low frequency.

The monopole is the limiting case of a pulsating sphere when its radius tends to zero; however, to have a nonzero pressure field, the amplitude of the sphere's vibration velocity must increase as the inverse of the radius squared. Thus, it tends to infinity when $r \rightarrow 0$. A major conclusion is that a monopole is an ideal model and not a real physical source because it is not defined mathematically when $r = 0$.

The sound pressure field radiated by a monopole has the form given by Eq. (1) but is characterized by its strength S :

$$p(M, M_0) = S \frac{\exp(-jkr)}{r} = S 4\pi g(M, M_0) \quad (6)$$

where

$$g(M, M_0) = \frac{\exp(-jkr)}{4\pi r}$$

is called the Green's function for a free field. (It is the basic tool for integral representation of radiated sound pressure fields (see Section 4).)

2.2 Sound Radiated by Two Pulsating Spheres in Opposite Phase, Dipole

A second elementary source consists of two equal out-of-phase pulsating spheres separated by a distance $2d$.

Because the problem is linear, the total sound pressure radiated is the sum of that radiated independently by each pulsating sphere:

$$p(M, M_0) = V \rho_0 c \frac{jka^2}{1 + jka} \exp(jka) \times \left[\frac{\exp(-jkr_1)}{r_1} - \frac{\exp(-jkr_2)}{r_2} \right] \quad (7)$$

where M_1 and M_2 are the centers of the two spheres; $r_1 = |MM_1|$ and $r_2 = |MM_2|$ are the distances from those centers to point M , and M_0 is the point located at middistance from the centers of the two spheres.

The dipole is the limiting case of this physical problem. One first assumes that the pulsating spheres are monopoles of opposite strength of the form $S = D/2d$. The sound pressure is thus given by

$$p(M, M_0) = D \left\{ \left[\frac{\exp(-jkr_1)}{r_1} - \frac{\exp(-jkr_2)}{r_2} \right] / 2d \right\} \quad (8)$$

The dipole is the limiting case when the distance d tends to zero, that is, by using the definition of the derivative in the direction $\overrightarrow{M_1 M_2}$:

$$p(M, M_0) = D 4\pi \frac{\partial g(M, M_0)}{\partial d} = D \left\{ \frac{\partial}{\partial x} \left[\frac{\exp(-jkr)}{r} \right] d_x + \frac{\partial}{\partial y} \left[\frac{\exp(-jkr)}{r} \right] d_y + \frac{\partial}{\partial z} \left[\frac{\exp(-jkr)}{r} \right] d_z \right\} \quad (9)$$

where (d_x, d_y, d_z) are the components of the unit vector of direction $\overrightarrow{M_1 M_2}$, which indicates the axis of the dipole. The dipole source strength is D .

The dipole is a theoretical model only and not a real physical source because it consists of two monopoles.

An elementary calculation leads to another expression for the sound pressure radiated by a dipole:

$$p(M, M_0) = D \frac{\partial}{\partial r} \left[\frac{\exp(-jkr)}{r} \right] \times \left(\frac{\partial r}{\partial x} d_x + \frac{\partial r}{\partial y} d_y + \frac{\partial r}{\partial z} d_z \right) \quad (10)$$

The sound pressure field has now a strong directivity. In particular, in the plane normal to the axis of the dipole the radiated pressure is zero and in the direction of the axis the pressure is maximum.

2.3 Multipoles

Let us consider the pressure field of a monopole. It satisfies the homogeneous Helmholtz equation in the entire space, except at the source point:

$$\Delta g(M, M_0) + k^2 g(M, M_0) = 0 \quad \text{for all points } M \neq M_0 \quad (11)$$

where Δ is the Laplacian operator.

One can derive this equation and obtain the following result:

$$\frac{\partial^{n+m+q}}{\partial x^n \partial y^m \partial z^q} [\Delta g(M, M_0) + k^2 g(M, M_0)] = 0 \quad \text{for all points } M \neq M_0 \quad (12)$$

Because the order of derivation is not important, this equation can also be written as

$$\Delta g_{nmq}(M, M_0) + k^2 g_{nmq}(M, M_0) = 0 \quad \text{for all points } M \neq M_0 \quad (13)$$

where

$$g_{nmq}(M, M_0) = \frac{\partial^{n+m+q}}{\partial x^n \partial y^m \partial z^q} g(M, M_0) \quad \text{for all points } M \neq M_0 \quad (14)$$

All the functions $g_{nmq}(M, M_0)$, are solutions of the homogeneous Helmholtz equation, except at the source point M_0 . They constitute a set of elementary solutions that can be used to represent radiated sound fields. If $n = m = q = 0$, the corresponding solution is a monopole. The first derivative corresponds to dipole pressure fields; for example, $n = 1, m = q = 0$, is the pressure field created by a dipole of axis x , the two others by dipoles of axis y and z (the dipole described in Section 1.2 is a linear combination of these three elementary dipoles). The second derivatives are characteristic of quadrupoles and higher derivatives of multipole pressure fields characterized by more and more complicated directivity patterns.

2.4 Equivalent Source Decomposition Technique

The functions $g_{nmq}(M, M_0)$ constitute an infinite number of independent pressure field solutions of the Helmholtz equation in whole space, except at the point source M_0 and verify the Sommerfeld conditions at an infinite distance from the source point. This set of functions can be used to express the sound radiated by vibrating objects. This is commonly called the *equivalent sources decomposition* technique. Let us consider a closed vibrating surface and study the sound pressure radiated into the surrounding external acoustic medium.

The solution is calculated as the linear combination of multipole contributions:

$$p(M) = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \sum_{q=0}^{\infty} A_{nmq} g_{nmq}(M, M_0) \quad (15)$$

where M_0 is located inside the vibrating surface and the coefficients A_{nmq} of the expansion must be adjusted in order to agree with the normal velocity of the vibrating surface.

Equation (15) satisfies the Helmholtz equation and the radiation conditions at infinity because it is the sum of functions verifying these conditions. To be the solution of the problem, it has also to verify the velocity continuity on the vibrating surface:

$$\frac{-1}{j\omega\rho} \frac{\partial p}{\partial n}(Q) = V_n(Q) \quad (16)$$

where $\partial p / \partial n$ is the normal derivative and $V_n(Q)$ is the normal velocity of the point Q of the vibrating surface.

Substituting Eq. (15) into Eq. (16) one obtains

$$\sum_{n=0}^{\infty} \sum_{m=0}^{\infty} \sum_{q=0}^{\infty} A_{nmq} \frac{\partial g_{nmq}}{\partial n}(Q, M_0) = -j\omega\rho V_n(Q) \quad (17)$$

Numerically, only a finite number of functions can be considered in the evaluation of Eq. (17), and, thus, a finite number of equations is necessary to calculate the unknown amplitudes A_{nmq} . The simplest possibility is to verify Eq. (17) at a number of points on the surface equal to the number of terms of the expansion:

$$\sum_{n=0}^N \sum_{m=0}^M \sum_{q=0}^Q A_{nmq} \frac{\partial g_{nmq}}{\partial n}(Q_i, M_0) = -j\omega\rho V_n(Q_i) \quad \text{for } i = 0, 1, 2, \dots, N + M + Q \quad (18)$$

This is a linear system that can be solved to obtain the unknown term A_{nmq} . Introducing the corresponding values in Eq. (15) allows one to calculate the radiated sound pressure field.

The equivalent source technique has been applied in several studies⁵⁻¹² in the form presented or in other forms. Among different possibilities one can use several monopoles placed at different locations inside the vibrating surface instead of multipoles located at one point source. A second possibility is to adapt the sources to a particular geometry, for example, cylindrical harmonics to predict radiation from cylinders.

As an example the following two-dimensional case is presented (see Fig. 1). The calculations were made by Pavic.¹² For low wavenumbers the reconstructed velocity field shows some small discrepancies at the corners, particularly when they are close to the vibrating part of the box. (See Fig 2.)

3 WAVE APPROACH

The analysis presented in this section treats a particular case that is quite different from real structures. However, it is a fruitful approach because basic radiation phenomenon can be demonstrated analytically. In particular, the fundamental notion of radiating and nonradiating structural vibration waves presented here is essential for a good understanding of sound radiation phenomena.

Figure 1 Box-type structure geometry (dimensions in metres).

3.1 Radiation from a Traveling Wave on an Infinite Vibrating Plane

Let us consider an infinite plane where a propagating wave is traveling, creating a velocity field in the

z direction, of the form

$$V_z(x, y) = A \exp(j\lambda x + j\mu y) \quad (19)$$

where $V_z(x, y)$ is the velocity in the z direction (normal to the plane), A is the amplitude of the velocity, and λ, μ are the wavenumbers in the x and y directions. A physical illustration of the problem is the velocity field produced by a plate in bending vibration, located in the plane $z = 0$.

Let us study the sound pressure created by this source, in the infinite medium located in the half space $z > 0$. The sound pressure $p(x, y, z)$ must satisfy the Helmholtz equation in the half space [Eq. (20)] and the continuity of acoustic velocity in the z direction and the velocity field (1) [Eq. (21)]:

$$\Delta p + k^2 p = 0 \quad (20)$$

where $k = \omega/c$ is the acoustic wave number, ω is the angular frequency, and c is the speed of sound.

$$V_z(x, y) = \frac{j}{\omega \rho_0} \frac{\partial p}{\partial z}(x, y, 0) \quad (21)$$

where ρ_0 is the fluid density.

Figure 2 Calculated radiated sound pressure at three wavenumbers (top) and reconstructed velocity field on the boundary (bottom). High-pressure level corresponds to white and low to black. The equivalent source positions are indicated by points inside the box, their strengths are indicated by the darkness. (From Pavic.¹²)

The velocity continuity over the plane implies a sound pressure field having the same form in the x and y directions as the propagating wave Eq. (19):

$$p(x, y, z) = F(z) \exp(j\lambda x + j\mu y) \quad (22)$$

Using Eqs. (20)–(22), one can obtain the following equations for $F(z)$:

$$\frac{d^2 F}{dz^2}(z) + (k^2 - \lambda^2 - \mu^2)F(z) = 0 \quad (23)$$

$$\frac{dF}{dz}(0) = -j\omega\rho_0 A \quad (24)$$

The solution of Eqs. (23) and (24) has two different forms depending on the frequency. Let us first define the cutoff frequency ω_{co} :

$$\omega_{co} = c\sqrt{\lambda^2 + \mu^2} \quad (25)$$

If $\omega > \omega_{co}$, the solution is

$$F(z) = -\frac{\omega\rho_0}{k_z} A \exp(-jk_z z) \quad (26)$$

$$\text{and} \quad k_z = \sqrt{k^2 - \lambda^2 - \mu^2} \quad (27)$$

The sound pressure in the acoustic medium can be obtained from Eq. (22):

$$p(x, y, z) = -\frac{\omega\rho_0}{k_z} A \exp(j\lambda x + j\mu y - jk_z z) \quad (28)$$

If $\omega < \omega_{co}$, the solution is

$$F(z) = j\frac{\omega\rho_0}{\gamma_z} A \exp(-\gamma_z z) \quad (29)$$

$$\text{and} \quad \gamma_z = \sqrt{-k^2 + \lambda^2 + \mu^2} \quad (30)$$

The sound pressure is given by

$$p(x, y, z) = j\frac{\omega\rho_0}{\gamma_z} A \exp(j\lambda x + j\mu y - \gamma_z z) \quad (31)$$

Equation (28) indicates that the sound pressure wave propagates in the z direction, while the solution given by Eq. (31) diminishes with the distance from the plane. This is of major importance and indicates that a vibration wave propagating on a plane can produce two types of acoustic phenomena, which depend on frequency. In the first case noise is emitted far from the plate as opposed to the second case where the sound pressure amplitude decreases exponentially with the distance from the plane. This basic result is of great importance for understanding radiation phenomena.

3.2 Radiating and Nonradiating Waves

A transverse vibration wave traveling on a plane can produce two types of acoustic waves, commonly called radiating waves and nonradiating waves for reasons explained in this section.

3.2.1 Radiating Waves The sound pressure is of the type given in Eq. (28). It is a wave propagating in directions x , y , and z . The dependence of the wavenumbers λ , μ and k_z on the angles θ and φ can be written as

$$\begin{aligned} \lambda &= k \sin(\varphi) \sin(\theta) \\ \mu &= k \cos(\varphi) \sin(\theta) \\ k_z &= k \cos(\theta) \end{aligned} \quad (32)$$

where $\varphi = \arctan(\lambda/\mu)$ and $\theta = \arccos(\sqrt{1 - \omega_{co}^2/\omega^2})$.

When $\theta = 0$, the sound wave is normal to the plane; when $\theta = \pi/2$, it is grazing. Using the expression for θ versus frequency, one can see that just above the cutoff frequency, $\theta = \pi/2$ ($k_z = 0$) and the radiated wave is grazing, then the propagation angle θ decreases with frequency and finally reaches 0 at high frequency, meaning that the sound wave tends to be normal to the plane. Directivity gives a first description of the radiation phenomenon. A second one characterizing energetically the noise emitted is also of interest. The intensity propagated by a sound wave given in Eq. (33) is the basic quantity. However, in order to have a nondimensional quantity, the radiation factor σ given in Eq. (34) is generally preferred to indicate radiation strength. Due to the infinite nature of the vibrating surface, the radiation factor is calculated for a unit area; the ratio of the sound power radiated and the square of the velocity of a unit area times the acoustic impedance $\rho_0 c$, reduces to the ratio of the sound intensity component in the z direction and the square of the modulus of the vibration wave velocity amplitude. It indicates the efficiency of the vibration field to radiate noise far from the vibrating object:

$$\mathbf{I} = \begin{Bmatrix} I_x \\ I_y \\ I_z \end{Bmatrix} = \frac{1}{2} |A|^2 \frac{\omega\rho_0}{k_z^2} \begin{Bmatrix} -\lambda \\ -\mu \\ k_z \end{Bmatrix} \quad (33)$$

$$\sigma = \frac{I_z}{\rho_0 c |A|^2} \quad (34)$$

The sound intensity vector shows that the sound wave follows the propagation of the vibration wave in the (x, y) directions but also propagates energy in the z direction.

After calculation, the radiation factor can be expressed simply as

$$\sigma = \frac{1}{\sqrt{1 - \omega_{co}^2/\omega^2}} \quad (35)$$

Figure 3 presents the radiation factor versus frequency. Just above the cutoff frequency it tends to infinity;

Figure 3 Radiation factor σ versus frequency ratio $(\omega_c/\omega)^2$.

then it decreases and tends to unity at high frequency. Of course, an infinite radiation factor is not realistic. Since fluid loading has not been considered in this standard analysis, the vibration wave amplitude is not affected by the sound pressure created. In reality, just above the cutoff frequency the radiated pressure tends to be infinite and blocks the vibration of the plane. Consequently, when the radiation efficiency tends to infinity, the wave amplitude tends to zero and the radiated sound pressure remains finite.

It is interesting to notice the relation between the angle of the radiated wave and the radiation efficiency:

$$\theta = \arccos\left(\frac{1}{\sigma}\right) \quad (36)$$

So, for high values of the radiation factor, grazing waves are radiated, and for values close to unity the radiation is normal to the plane. This tendency is quite general and remains true in more complicated cases like finite plates.

3.2.2 Nonradiating Waves Nonradiating waves are also called evanescent waves in the literature. The pressure is of the form given in Eq. (31) that corresponds to frequencies below the cutoff frequency. The intensity vector of the sound wave can be calculated easily:

$$\mathbf{I} = \begin{Bmatrix} I_x \\ I_y \\ I_z \end{Bmatrix} = \frac{1}{2} |A|^2 \frac{\omega \rho_0}{\gamma_z^2} \exp(-2\gamma_z z) \begin{Bmatrix} -\lambda \\ -\mu \\ 0 \end{Bmatrix} \quad (37)$$

The sound wave generated is different from those observed in the radiating wave case. Sound intensity still propagates along the plane but no longer in the z direction. Having the intensity component in the z direction equal to zero does not mean an absolute

silence exists in the fluid medium but that the pressure amplitude decreases exponentially with distance from the plane. To hear the acoustic effect of the vibration wave, one has to listen in the vicinity of the plane.

Obviously, the radiation factor is equal to zero, and no directivity of the sound field can be defined because of the vanishing nature of the radiated wave.

3.3 Radiation from a Baffled Plane Vibration Field

3.3.1 Plane Wave Decomposition of a Vibration Field The previous results can be extended to finite vibrating plane surfaces very easily. Let us consider a vibration field on an infinite plane of the form:

$$V_z(x, y) = \begin{cases} 0 & \text{if } (x, y) \notin S \\ V_p(x, y) & \text{if } (x, y) \in S \end{cases} \quad (38)$$

where $V_p(x, y)$ is the transverse velocity of surface S .

The following analysis is based on the two-dimensional space Fourier transform of the vibration field (38):

$$\tilde{V}_z(\lambda, \mu) = \iint_S \exp[-j(\lambda x + \mu y)] V_p(x, y) dx dy \quad (39)$$

Because the transverse velocity is zero except on the surface S , the integral over the infinite plane reduces to the integral over the surface S .

Calculating the inverse transform gives the velocity vibration field on the whole plane:

$$V_z(x, y) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \frac{\tilde{V}_z(\lambda, \mu)}{4\pi^2} \times \exp[j(\lambda x + \mu y)] d\lambda d\mu \quad (40)$$

This expression demonstrates that each vibration field defined on the surface S can be decomposed in an infinite number of propagating waves having the same form used in Eq. (19), where $A = \tilde{V}_z(\lambda, \mu)/4\pi^2$.

3.3.2 Sound Pressure Radiated Because the problem is linear, the sound pressure radiated by a group of waves traveling on the plane is the sum of the pressures radiated by each wave separately. Section 4 demonstrates that two types of waves exist which depend on frequency: radiating waves and nonradiating waves. Thus, the radiated sound pressure can be calculated by separating the vibration waves into two groups: $p_R(x, y, z)$, the pressure due to radiating waves, and $p_{NR}(x, y, z)$, the pressure due to nonradiating waves. Then, the total sound pressure radiated is the sum of the two terms:

$$p(x, y, z) = p_R(x, y, z) + p_{NR}(x, y, z) \quad (41)$$

where

$$p_{NR}(x, y, z) = \iint_{\sqrt{\lambda^2 + \mu^2} > \omega/c} \frac{j\omega\rho_0}{\sqrt{\lambda^2 + \mu^2 - (\omega/c)^2}} \times \frac{\tilde{V}_z(\lambda, \mu)}{4\pi^2} \exp[j\lambda x + j\mu y - \sqrt{\lambda^2 + \mu^2 - (\omega/c)^2} z] d\lambda d\mu \quad (42)$$

$$p_R(x, y, z) = \iint_{\sqrt{\lambda^2 + \mu^2} < \omega/c} \frac{\omega\rho_0}{\sqrt{(\omega/c)^2 - \lambda^2 - \mu^2}} \times \frac{\tilde{V}_z(\lambda, \mu)}{4\pi^2} \exp[j\lambda x + j\mu y - j\sqrt{(\omega/c)^2 - \lambda^2 - \mu^2} z] \times d\lambda d\mu \quad (43)$$

Several interesting points can be understood from Eqs. (42) and (43):

1. The pressure due to the radiating waves is easier to calculate than the one due to nonradiating waves because the integration domain is finite in Eq. (43) and infinite in Eq. (42).
2. If one is interested in the sound pressure in the far field of the radiating surface, the part due to nonradiating waves can be neglected because of its exponential decay with z .
3. In the near field of the radiating surface both types of waves contribute to the pressure.
4. To reduce the sound power radiated by the vibration field one has to decrease the amplitude of the radiating wave. This explains why reducing the vibration level can have a very small effect on the radiated sound.

3.3.3 Wave Decomposition of the Vibration Field of a Piston Let us consider a rectangular piston of length $2a$ and width $2b$. The vibration field of the baffled piston is given by Eq. (44):

$$V_z(x, y) = \begin{cases} 1 & \text{if } (x, y) \in [-a, +a] \times [-b, +b] \\ 0 & \text{if } (x, y) \notin [-a, +a] \times [-b, +b] \end{cases} \quad (44)$$

A simple calculation gives the two-dimensional space Fourier transform:

$$\tilde{V}_z(\lambda, \mu) = 4 \frac{\sin(\lambda a)}{\lambda} \frac{\sin(\mu b)}{\mu} \quad (45)$$

Figure 4 Space Fourier transform $\left[\tilde{V}_z(\lambda, 0)/4ab = \sin(\lambda a)/\lambda a\right]$ of the rectangular piston vibration field versus λa .

Figure 4 presents the variation with λa of the function

$$\frac{\tilde{V}_z(\lambda, 0)}{4ab} = \frac{\sin(\lambda a)}{\lambda a}$$

It can be concluded that the waves of greatest amplitude are those with low values of λa . Of course, the same tendency applies for $\tilde{V}_z(0, \mu)/4ab$, and it can be concluded that waves dominating the piston motion are those with small values of λa and μb .

Substituting Eq. (45) into Eqs. (42) and (43) and calculating the integral leads to the sound pressure field radiated by the rectangular piston. However, our goal here is not to carry out this calculation but to use wave decomposition to understand the phenomenon.

The radiating waves are frequency dependent and have wavenumbers located in a circle given by

$$\lambda^2 + \mu^2 < (\omega/c)^2 \quad (46)$$

This circle decomposes the wavenumber plane into two domains: inside the circle are located wavenumber components of radiating waves, and outside are located those of nonradiating waves. All wavenumber components participate in the vibration field, but only the radiating wave components contribute to sound power radiation. One can conclude that the proportion of radiating waves is a good indicator of the radiation efficiency of the piston.

At low frequency the radius of the circle is small and the proportion of radiating waves is small compared to that of nonradiating waves. As a consequence, the radiation efficiency is much less than one. When the frequency increases the radius of the circle does the same, and more and more wavenumber components become radiating, leading to a greater radiation efficiency of the piston. Finally due to the decrease of wave amplitude with wavenumber [see Eq. (45)], at a sufficiently high frequency all nonradiating components

Figure 5 Radiating (light grey) and nonradiating (dark grey) wavenumber components of the piston vibration field. The left figure shows a lower frequency than the right figure.

have very low amplitudes and do not contribute significantly to the vibration field and sound radiation. This means that all wave components which participate significantly in the vibration field radiate noise and the radiation factor tends toward unity. This point is illustrated in Fig. 5, however, for the sake of simplicity, only the one-dimensional representation is presented. The radiating components are located in the light grey wavenumber region and the nonradiating in the dark grey region; when the frequency increases the light grey part increases too.

The wave analysis of vibration fields described here for the rectangular piston can be extended directly to all planar baffled sources. It demonstrates quite simply a fundamental property of radiation phenomena. Reduction of vibration levels is not equivalent to reduction of radiated noise. If the decrease of vibration velocity is due to that of nonradiating wave components, the sound power radiated remains unchanged.

3.4 Sound Radiated by an Infinite Plate

Up to now the velocity of vibration waves was defined independently of the mechanical structure. Of course, in real cases one has to take into account the structure where the propagation takes place. Let us consider a thin plate; the equation of motion is

$$-\omega^2 MW(x, y) + D \left(\frac{\partial^4 W}{\partial x^4} + 2 \frac{\partial^4 W}{\partial x^2 \partial y^2} + \frac{\partial^4 W}{\partial y^4} \right) = 0 \quad (47)$$

where M is the mass per unit area of the plate, D is the bending stiffness, and $W(x, y)$ is the transverse displacement.

If a propagating wave in Eq. (48) is traveling on the plate, it must satisfy the equation of motion Eq. (47). That is to say:

$$W(x, y) = B \exp(j\lambda x + j\mu y) \quad (48)$$

$$[-\omega^2 M + D(\lambda^2 + \mu^2)] B \times \exp(j\lambda x + j\mu y) = 0 \quad (49)$$

To be satisfied, Eq. (49) introduces a relation between ω and (λ, μ) :

$$\omega = \sqrt{\frac{D}{M}} (\lambda^2 + \mu^2) \quad (50)$$

When Eq. (50) is satisfied, the propagating wave corresponds to a natural bending wave in the plate. To fit with the calculation of the sound radiation from a velocity propagating wave made in Section 2, one can calculate the vibration velocity associated with the bending displacement, Eq. (48):

$$V_z(x, y) = j\omega B \exp(j\lambda x + j\mu y) \quad (51)$$

Calculations made in Section 2.3 can be used here by replacing the wave amplitude A by $j\omega B$; however, the cutoff frequency limiting the frequency domain of radiating and nonradiating waves must take into account Eq. (50).

The cutoff frequency depends on wavenumbers λ and μ through Eq. (25):

$$\omega_{co} = c\sqrt{\lambda^2 + \mu^2}$$

In addition at each frequency and in particular at the cutoff frequency, ω_{co} , the wavenumbers (λ, μ) must also satisfy Eq. (50):

$$\omega_{co} = \sqrt{\frac{D}{M}} (\lambda^2 + \mu^2)$$

Both relations can be verified simultaneously at only one frequency:

$$\omega_{co} = \omega_c = c^2 \sqrt{\frac{M}{D}}$$

where ω_c is the critical frequency. This frequency depends on the plate characteristics and speed of sound. With standard expressions of mass per unit area of the plate and bending stiffness, the critical frequency can be written

$$\omega_c = c^2 \sqrt{\frac{\rho_p(1-\nu^2)12}{E}} \frac{1}{h} \quad (52)$$

where ρ_p is the mass per unit volume, E the Young's modulus, ν the Poisson ratio, and h the thickness of the plate.

Thus, radiation from an infinite plate in bending motion is characterized by one cutoff frequency, called the critical frequency. For $\omega < \omega_c$ the sound wave is of the form in Eq. (31), it is evanescent in the z direction and the vibration wave is nonradiating. For $\omega > \omega_c$ the acoustic wave is of the form in Eq. (28); it is propagating in the z direction, and the vibration wave is radiating.

The radiation factor of an infinite plate has the form given in Fig. 4; below the critical frequency it is equal to zero, just above it tends to infinity and is asymptotic to one at high frequency. It is shown later that this trend is realistic to describe the sound radiation from finite plates.

To give a second explanation for the phenomenon, one can compare the velocity of bending waves c_B in the plate [Eq. (53)] and the speed of sound (see Fig. 6):

$$c_B = \sqrt{\omega} \sqrt[4]{\frac{D}{M}} \quad (53)$$

Let us consider a propagating acoustic wave generated by the vibration wave in the plate. Due to the continuity of plate and acoustic velocities, the projection of

Figure 6 Acoustic and bending wave velocities versus frequency. The intersection of the two curves occurs at the critical frequency.

the acoustic wavelength on the plane of the plate must be equal to the bending wavelength:

$$\frac{c_B}{\omega} = \frac{c}{\omega} \sin(\theta) \Rightarrow \sin(\theta) = \frac{c}{c_B} \quad (54)$$

where θ is the angle between the direction of propagation of the acoustic wave and the normal to the plane of the plate. From Eq. (54) it is easy to see that this angle only exists when $c_B > c$, that is, when bending waves are supersonic. For $c_B < c$ (subsonic bending waves), the sound wave no longer propagates in the z direction.

Finally using Eq. (53) for the bending wave speed, one can conclude that below the critical frequency bending waves are subsonic while above they are supersonic. A parallel can be established between supersonic and radiating waves and also between subsonic and non-radiating waves.

4 INTEGRAL EQUATION FOR NOISE RADIATION

In this section the main method used for the prediction of the sound pressure radiated by the vibrating object is presented. It is based on the concept of Green's function; that is, an elementary solution of the Helmholtz equation used to calculate the radiated sound field from the vibrating objects. The method is related to Huygens' principle where objects placed in an acoustic field appear as secondary sources.

4.1 Kirchhoff Integral Equation

Let us consider the following acoustical problem. Acoustic sources $S(M)$ are emitting noise in an infinite acoustic medium. An object is placed in this medium, which occupies the volume V inside the surface \bar{V} .

The sound pressure has to satisfy the following equations:

$$\Delta p(M) + k^2 p(M) = S(M) \quad (55)$$

where M is a point in the infinite space outside the object of surface \bar{V} .

At each point Q on the surface \bar{V} the acoustic normal velocity must be equal to that of the vibrating object $v_n(Q)$ (in the following the outer normal to the fluid medium is considered):

$$v_n(Q) = \frac{j}{\omega \rho} \frac{\partial p}{\partial n}(Q) \quad (56)$$

where $\partial/\partial n$ is the derivative of the sound pressure normal to the surface \bar{V} at point Q .

Let us also consider the following problem that characterizes the sound pressure field created by a point source located at M_0 :

$$\Delta g(M, M_0) + k^2 g(M, M_0) = \delta(M - M_0) \quad (57)$$

where $\delta(M - M_0)$ is the Dirac delta function.

This is the fundamental equation satisfied by the Green's function. It has also to satisfy the Sommerfeld condition at infinity; $g(M, M_0)$ is named the Green's function in infinite space. It corresponds to the pressure field of a monopole of strength $1/4\pi$ placed at point M_0 .

$$g(M, M_0) = \frac{\exp(-jkr)}{4\pi r} \quad \text{where } r = |M - M_0| \quad (58)$$

Using the previous equations one can write

$$\begin{aligned} & \iiint_{R^3-V} [\Delta p(M) + k^2 p(M)] g(M, M_0) dM \\ &= \iiint_{R^3-V} S(M) g(M, M_0) dM \end{aligned} \quad (59)$$

Then transforming the integral of the left hand side of the equation by use of the Ostrogradsky formula, one obtains

$$\begin{aligned} & \iiint_{R^3-V} [\Delta g(M, M_0) + k^2 g(M, M_0)] p(M) dM \\ &= \iiint_{R^3-V} S(M) g(M, M_0) dM \\ & \quad - \iint_{\bar{V}} \frac{\partial p}{\partial n}(Q) g(Q, M_0) - \frac{\partial g}{\partial n}(Q, M_0) p(Q) dQ \end{aligned}$$

Finally taking into account the fundamental equation verified by the Green's function and the property of the Dirac delta function, the sound pressure at point M_0 can be expressed as follows:

$$\begin{aligned} p(M_0) &= \iiint_{R^3-V} S(M) g(M, M_0) dM \\ & \quad - \iint_{\bar{V}} \frac{\partial p}{\partial n}(Q) g(Q, M_0) \\ & \quad - \frac{\partial g}{\partial n}(Q, M_0) p(Q) dQ \end{aligned} \quad (60)$$

This expression is known as the Kirchhoff integral equation. Two terms appear: the first is the direct field; the second is the diffracted the field. The direct field can be interpreted as the superposition of monopoles located at source points in the volume occupied by the fluid medium; the sound source amplitude being the monopole strength. The diffracted field is the superposition of monopoles of strength $\partial p / \partial n(Q)$ and dipoles of strength $p(Q)$ located on the surface of the object. The presence of the object in the sound field of the sound source

produces secondary sources of monopole and dipole types responsible for the diffraction of the sound.

To calculate the sound pressure at point M_0 in the volume, it is necessary to know the boundary sound pressure and velocity on the surface \bar{V} . In our case the velocity is given, but the pressure is unknown. The general expression, Eq., (60) reduces to

$$\begin{aligned} p(M_0) &= \iiint_{R^3-V} S(M) g(M, M_0) dM \\ & \quad - \iint_{\bar{V}} -j\omega\rho v_n(Q) g(Q, M_0) \\ & \quad - \frac{\partial g}{\partial n}(Q, M_0) p(Q) dQ \end{aligned} \quad (61)$$

To determine the sound pressure at the boundary one can use the previous integral equation for point Q_0 situated on the surface. However, in this case, due to the presence of the Dirac delta function on the boundary surface, the expression for the pressure is modified:

$$\begin{aligned} \frac{p(Q_0)}{2} &= \iiint_{R^3-V} S(M) g(M, Q_0) dM \\ & \quad - \iint_{\bar{V}} \frac{\partial p}{\partial n}(Q) g(Q, Q_0) \\ & \quad - \frac{\partial g}{\partial n}(Q, Q_0) p(Q) dQ \end{aligned} \quad (62)$$

or for a given normal velocity on the object:

$$\begin{aligned} \frac{p(Q_0)}{2} &= \iiint_{R^3-V} S(M) g(M, Q_0) dM \\ & \quad - \iint_{\bar{V}} -j\omega\rho v_n(Q) g(Q, Q_0) \\ & \quad - \frac{\partial g}{\partial n}(Q, Q_0) p(Q) dQ \end{aligned} \quad (63)$$

This equation is generally solved numerically by the collocation technique in order to obtain the boundary pressure, which is then used in Eq (61) to calculate the sound pressure in the fluid medium. The Kirchhoff integral equation presents a problem in the prediction of the radiated sound pressure, known as singular frequencies, where the calculation is not possible. The singular frequencies correspond to the resonance frequencies of the acoustic cavity having the volume V of the object responsible for diffraction. Different methods can be used to avoid the problem of singular frequency; some of them are described in the literature.³²⁻³⁶

The same approach can be used for internal cavity problems. The Kirchhoff integral equation has the form of Eqs. (64) and (65) for points, respectively, inside the cavity of volume V and on the boundary surface \bar{V} :

$$p(M_0) = \iiint_V S(M)g(M, M_0) dM - \iint_{\bar{V}} -j\omega\rho v_n(Q)g(Q, M_0) - \frac{\partial g}{\partial n}(Q, M_0)p(Q) dQ \quad (64)$$

$$\frac{p(Q_0)}{2} = \iiint_V S(M)g(M, Q_0) dM - \iint_{\bar{V}} -j\omega\rho v_n(Q)g(Q, Q_0) - \frac{\partial g}{\partial n}(Q, Q_0)p(Q) dQ \quad (65)$$

In this case, the problem of singular frequency is physically realistic and corresponds to resonances of the cavity.

4.2 Rayleigh Integral Equation

Other Kirchhoff-type integral equations can be obtained using the modified Green's functions. For example, let us consider the Green's function $g_0(M, M_0)$ that satisfies

$$\Delta g_0(M, M_0) + k^2 g_0(M, M_0) = \delta(M - M_0) \quad (66)$$

$$\text{and} \quad \frac{j}{\omega\rho} \frac{\partial g_0}{\partial n}(Q, M_0) = 0 \quad \forall Q \in \bar{V} \quad (67)$$

Using this new Green's function in Eq. (61) produces a modified integral equation:

$$p(M_0) = \iiint_V S(M)g_0(M, M_0) dM - \iint_{\bar{V}} -j\omega\rho v_n(Q)g_0(Q, M_0) dQ \quad (68)$$

This integral equation is much simpler than Eq. (61) because it is explicit, and the radiated sound pressure can be directly calculated without previous calculation of boundary unknowns. Several other integral equations derived from the basic Kirchhoff integral can be obtained by modification of the Green's function. One has to notice, as a general rule, that the simplification of the integral equation is balanced by the

difficulty of calculation of the modified Green's function. However, in one particular case, one can simplify the integral equation and keep a simple Green's function; it is the case of a planar radiator, which leads to the Rayleigh integral equation. In this case the Green's function is $g_R(M, M_0)$, and it satisfies Eqs. (69) and (70):

$$\Delta g_R(M, M_0) + k^2 g_R(M, M_0) = \delta(M - M_0) + \delta(M - M_0^{im}) \quad (69)$$

$$\text{and} \quad \frac{j}{\omega\rho} \frac{\partial g_R}{\partial n}(Q, M_0) = 0 \quad \forall Q \in \bar{V} \quad (70)$$

In this problem the surface \bar{V} is the plane $z = 0$, and the point M_0^{im} is the symmetrical point of M_0 relative to the plane \bar{V} . The Green's function is thus the sound pressure created by a monopole placed at M_0 and by its image source, which is a second monopole placed at point M_0^{im} . This Green's function is the superposition of both sound pressure fields:

$$g_R(M, M_0) = \frac{\exp(-jkr)}{4\pi r} + \frac{\exp(-jkr_{im})}{4\pi r_{im}} \quad \text{where } r = |M - M_0| \text{ and } r_{im} = |M - M_0^{im}| \quad (71)$$

The sound pressure field in the half space $z > 0$ can be calculated with the following integral equation:

$$p(M_0) = \iiint_V S(M)g_R(M, M_0) dM - \iint_{\bar{V}} -j\omega\rho v_n(Q)g_R(Q, M_0) dQ \quad (72)$$

When no volume sources are present, the equation reduces to

$$p(M_0) = \iint_{\bar{V}} j\omega\rho v_n(Q)g_R(Q, M_0) dQ \quad (73)$$

In addition, because point Q is located on the plane, one has $r = r_{im}$ and the Rayleigh Green's function is written as

$$g_R(Q, M_0) = \frac{\exp(-jkr)}{2\pi r}$$

Finally, the Rayleigh integral equation, Eq. (74), is obtained (Rayleigh first integral formula),

$$p(M_0) = \iint_{\bar{V}} j\omega\rho v_n(Q) \frac{\exp(-jkr)}{2\pi r} dQ \quad (74)$$

This equation is quite simple both in the integral equation and in the Green's function expression. The Raleigh integral equation relies on the concept of image sources and is restricted to planar radiators. Physically it demonstrates that the radiated sound pressure is the effect of the superposition of monopoles whose strength is proportional to the vibration velocity of the object.

One important point is that the equation is also valid for point Q_0 on the plate, which is different from the general Kirchhoff integral where a factor of $1/2$ must be introduced in the integral equation for points on the boundary surface.

5 SOUND RADIATION FROM FINITE PLATES AND MODAL ANALYSIS OF RADIATION¹³⁻³⁰

5.1 Plate Vibration Modes and Modal Expansion of the Radiated Pressure and Power

The plate under study is rectangular and simply supported. It is a simple case where the vibration modes are well known. The natural frequencies ω_{il} and the mode shapes $f_{il}(x, y)$ are given by

$$\omega_{il} = \sqrt{\frac{D}{M}} \left[\left(\frac{i\pi}{a} \right)^2 + \left(\frac{l\pi}{b} \right)^2 \right] \quad (75)$$

$$f_{il}(x, y) = \sin \left(\frac{i\pi}{a} x \right) \sin \left(\frac{l\pi}{b} y \right) \quad (76)$$

where D and M are the bending stiffness and mass per unit area of the plate, and a is the width and b the length.

The response of the plate can be calculated as a modal response superposition:

$$W(x, y) = \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} a_{il} f_{il}(x, y) \quad (77)$$

Assuming the plate is baffled, the sound pressure radiated can be calculated using the Rayleigh integral approach or the radiating and nonradiating wave decomposition technique. Here the Rayleigh integral approach is used. The normal velocity can be obtained from the plate displacement:

$$v_n(x, y) = \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} j\omega a_{il} f_{il}(x, y) \quad (78)$$

Substituting this expression in Eq. (74), the radiated sound pressure is

$$\begin{aligned} p(x_0, y_0, z_0) &= \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} j\omega \rho a_{il} \\ &\times \int_0^a \int_0^b f_{il}(x, y) \\ &\times g_R(x, y, 0; x_0, y_0, z_0) dx dy \quad (79) \end{aligned}$$

where

$$\begin{aligned} g_R(x, y, 0; x_0, y_0, z_0) &= \frac{\exp(-jkr)}{2\pi r} \text{ and} \\ r &= \sqrt{(x - x_0)^2 + (y - y_0)^2 + (z_0)^2} \quad (80) \end{aligned}$$

The sound radiation is generally characterized by the sound power radiated Π_{rad} in order to have a global quantity. The calculation can be made integrating the sound intensity normal to the plate on the plate surface. After calculation one obtains

$$\begin{aligned} \Pi_{\text{rad}} &= \frac{1}{2} \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} \sum_{s=1}^{\infty} \sum_{r=1}^{\infty} \omega^2 \rho \operatorname{Re} \left\{ a_{rs}^* a_{il} \right. \\ &\times \int_0^a \int_0^b \int_0^a \int_0^b f_{il}(x, y) g_R(x, y, 0; x_0, y_0, 0) \\ &\times f_{sr}(x_0, y_0) dx dy dx_0 dy_0 \left. \right\} \end{aligned}$$

this expression can be concisely written by introducing the radiation impedances Z_{ilrs} :

$$\Pi_{\text{rad}} = \frac{1}{2} \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} \sum_{s=1}^{\infty} \sum_{r=1}^{\infty} \omega^2 \operatorname{Re} \{ a_{rs}^* a_{il} Z_{ilrs} \} \quad (81)$$

where

$$\begin{aligned} Z_{ilrs} &= \int_0^a \int_0^b \int_0^a \int_0^b \rho f_{il}(x, y) \\ &\times g_R(x, y, 0; x_0, y_0, 0) f_{sr}(x_0, y_0) \\ &\times dx dy dx_0 dy_0 \quad (82) \end{aligned}$$

Radiation impedances are complex quantities, and they are often separated into two parts, radiation resistances R_{ilrs} and radiation reactances X_{ilrs} :

$$Z_{ilrs} = R_{ilrs} + jX_{ilrs} \quad (83)$$

When two different modes (i, l) and (r, s) are considered, Z_{ilrs} is known as the modal cross-radiation impedance. When the same mode (i, l) is considered, Z_{ilil} is known as the mode radiation impedance.

In Fig. 7 an example is presented. The first tendency that appears is that the cross-radiation resistance and reactance oscillate around zero when the frequency is varied, as opposed to the direct radiation resistance and reactance, which remain positive at all frequencies. However, the radiation reactance tends to be negligible at high frequencies, as opposed to radiation resistance which tends to the fluid acoustic impedance.

Figure 7 Radiation impedance of rectangular plate modes versus frequency. (a) Mode radiation resistance (solid line) and reactance (dashed line) for mode (1,1). (b) Modal cross-radiation resistance (dashed line) and reactance (solid line) for modes (1,1) and (1,3). (From Sandman.¹⁵)

Figure 8 Sound power level radiated by a baffled cylinder in water versus frequency. (a) Calculation with modal cross-radiation impedances and (b) calculation without modal cross-radiation impedances. (From Guyader and Laulagnet.²³)

In Fig. 8 the influence of neglecting cross-modal radiation impedance is presented. The case considered is extreme in the sense that the fluid is water and has an acoustic impedance more than a thousand times greater than air.

It can be seen in Fig. 8, that the general trend does not change when cross-modal radiation impedances are neglected. However, the power radiated by the cylinder can be modified by up to 10 dB at higher frequencies. This result is related to the heavy fluid loading of the structure. For light fluid loading the influence of cross-modal radiation impedances is quite small, and in general the cross-modal contributions are neglected. An approximate expression for the radiated sound power can be found:

$$\Pi_{\text{rad}} = \frac{1}{2} \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} \omega^2 |a_{il}|^2 R_{ilil} \quad (84)$$

To a first approximation the radiated sound power of the plate is the sum of the power radiated by each mode separately. The modal radiation is characterized by the modal resistance.

Modal resistances (or mode radiation factor σ_{mn} ,

$$\sigma_{mn} = \frac{R_{mnmn}}{\rho c N_{mn}}$$

where N_{mn} is the norm of the mode) of rectangular simply supported plates have been calculated in different studies using the Rayleigh integral approach or wave decomposition. The expressions of Wallace¹⁴ are given in Table 1, and Fig. 4 presents some typical results.

The main trends that can be observed in Fig. 9 are the radiation properties of plate modes below and above the mode critical frequency

$$\omega_c^{mn} = c \left[\left(\frac{n\pi}{b} \right)^2 + \left(\frac{m\pi}{a} \right)^2 \right]^{0.5}$$

Below ω_c^{mn} the radiation factor is small and decreases with frequency, while above it is equal to unity. In addition, depending on the mode shape, the radiation factor below ω_c^{mn} is small. This is due to the acoustic short-circuit effect. The short-circuit strength is larger for plate modes of high orders than low orders and also for odd mode orders rather than even ones.

To explain the phenomenon, let us consider the mode shape of Fig 10. When some parts of the plate are pushing the fluid (positive contribution), the other parts are pulling it (negative contribution). Both

Table 1 Radiation Factor σ_{mn} for Modes of Rectangular Simply Supported Plate

$k < k_{mn}$ and $k_x < k < k_y$	$\sigma_{mn} = \frac{k(k_x^2 + k_{mn}^2 - k^2)}{ak_x(k_{mn}^2 - k^2)^{3/2}}$
$k < k_{mn}$ and $k_x > k > k_y$	$\sigma_{mn} = \frac{k(k_y^2 + k_{mn}^2 - k^2)}{bk_y(k_{mn}^2 - k^2)^{3/2}}$
$k < k_{mn}$ and $k_x > k$ and $k_y > k$	$\sigma_{mn} = \frac{8k^2}{abk_x^2k_y^2} \left\{ 1 - (-1)^m \frac{\sin(ak)}{ak} - (-1)^n \frac{\sin(bk)}{bk} + (-1)^{m+n} \frac{\sin[k(a^2 + b^2)^{0.5}]}{k(a^2 + b^2)^{0.5}} \right\}$
$k < k_{mn}$ and $k_x < k$ and $k_y < k$	$\sigma_{mn} = k \left[\frac{k_x^2 + k_{mn}^2 - k^2}{ak_x(k_{mn}^2 - k^2)^{1.5}} + \frac{k_y^2 + k_{mn}^2 - k^2}{bk_y(k_{mn}^2 - k^2)^{1.5}} \right]$
$k > k_{mn}$	$\sigma_{mn} = \frac{k}{(k^2 - k_{mn}^2)^{0.5}}$
$k \approx k_{mn}$	$\sigma_{mn} = \frac{k}{3\pi} \left(\frac{a}{\sqrt{m}} + \frac{b}{\sqrt{n}} \right)$

Approximate values after Maidanik.¹³ n and m are mode indices, $k_{mn} = \left[\left(\frac{m\pi}{a} \right)^2 + \left(\frac{n\pi}{b} \right)^2 \right]^{0.5}$, $k_x = \frac{m\pi}{a}$, and $k_y = \frac{n\pi}{b}$.

**Figure 9** Radiation factor σ_{mn} of plate modes versus ratio of acoustic and plate mode wavenumbers: (a) modes (1,1) and (2,2) for different values of the length to width ratio of the plate and (b) high-order modes. (From Wallace.¹⁴)**Figure 10** Acoustical short circuit, edge, and corner radiation modes. (From Lesueur et al.⁴)

Figure 11 Polar coordinates used for plate sound radiation in the far field.

contributions cancel when the acoustic wavelength is greater than the flexural one. Physically the effect is equivalent to the case of a long boat (here the acoustic medium) excited by water waves of short wavelengths (the plate motion). The boat remains almost motionless (the radiated sound pressure is small). The importance of the short circuit depends on the mode shape. As a general rule the acoustical short circuit implies radiation of plate modes essentially produced by the boundary. Edge radiation modes exist when $k < k_{mn}$ and $k_x < k < k_y$ or $k < k_{mn}$ and $k_x > k > k_y$, and corner radiation modes when $k < k_{mn}$ and $k_x > k$ and $k_y > k$. See Fig 10.

5.2 Directivity of the Radiated Pressure Field

One important result concerning the radiated sound pressure in the far field of the plate is given here without derivation. Introducing polar coordinates for the acoustic medium (R, θ, ϕ) where R is the distance from the central point of the plate to a listening point in the far field, one has the geometry shown in Fig 11.

The radiated sound pressure in the far field of the plate is given by Eq. (85), and for a complete derivation one can consult Junger and Feit.¹

$$p(R, \theta, \Phi) = \rho \omega^2 \tilde{W} [-k \sin(\theta) \sin(\Phi), -k \sin(\theta) \cos(\Phi)] \frac{\exp(-jkR)}{R} \quad (85)$$

where $\tilde{W}(\lambda, \mu)$ is the double space Fourier transform of the plate displacement

$$\tilde{W}(\lambda, \mu) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \exp(-j\lambda x - j\mu y) \times W(x, y) dx dy \quad (86)$$

The application of this expression to plate modes of a simply supported rectangular plate is quite

elementary and gives the directivity of the sound pressure field radiated by the modes:

$$\tilde{W}_{rs}(\lambda, \mu) = \frac{2}{\pi} \frac{(r\pi/a)(s\pi/b)}{\left(\lambda^2 - \left(\frac{r\pi}{a}\right)^2\right) \left(\mu^2 - \left(\frac{s\pi}{b}\right)^2\right)} \times d(\lambda, \mu) \quad (87)$$

where

$$d(\lambda, \mu) = \begin{cases} \cos\left(\frac{\lambda a}{2}\right) \cos\left(\frac{\mu b}{2}\right), & r = \text{odd}, s = \text{odd} \\ -\cos\left(\frac{\lambda a}{2}\right) \sin\left(\frac{\mu b}{2}\right), & r = \text{odd}, s = \text{even} \\ -\sin\left(\frac{\lambda a}{2}\right) \cos\left(\frac{\mu b}{2}\right), & r = \text{even}, s = \text{odd} \\ \sin\left(\frac{\lambda a}{2}\right) \sin\left(\frac{\mu b}{2}\right), & r = \text{even}, s = \text{even} \end{cases} \quad (88)$$

The phenomena associated with the directivity of the modal radiated sound pressure in the far field are complicated. First, the symmetry and antisymmetry of plate modes produce symmetrical or antisymmetrical sound pressure fields. Consequently, the radiated sound pressure normal to the plate midpoint is zero if one index of the plate mode is even. To this effect one has to add the influence of the plate area. For a given frequency the number of radiation lobes increases with the plate dimensions (or for a given size of the plate the number of directivity lobes increases with frequency). Finally a maximum of the radiated sound pressure appears at an angle $\hat{\theta}$, which depends on the frequency and mode order as given by Eq. (89):

$$\hat{\theta} = \arcsin \left[\frac{c}{\omega} \sqrt{\left(\frac{r\pi}{a}\right)^2 + \left(\frac{s\pi}{b}\right)^2} \right] \quad (89)$$

The angle of maximum sound radiation exists only for frequencies above $c\sqrt{(r\pi/a)^2 + (s\pi/b)^2}$.

Figure 12 presents the phenomenon described here for the case of mode (15,15); the angle $\hat{\theta}$ of maximum radiation can be seen for frequencies above 2400 Hz.

5.3 Frequency Averaged Radiation from Plates Subjected to Rain on the Roof Excitation

For this type of excitation all the modes are equally excited, and the resonant modes in a frequency band of excitation have the same responses ($\langle \omega^2 |a_{il}|^2 \rangle$ constant for all resonant modes). The radiated sound power

Figure 12 Directivity of the sound pressure radiated in the far field by rectangular plate mode (15,15), for different frequencies. (From Guyader and Laulagnet.²³)

of the plate is the superposition of resonant mode radiation:

$$\begin{aligned} \langle \Pi_{\text{rad}} \rangle &= \sum_{i=\text{resonant}} \sum_{l=\text{resonant}} \rho \langle \omega^2 |a_{il}|^2 \rangle \langle R_{ilil} \rangle \\ &= \rho \langle \omega^2 |a_{il}|^2 \rangle \sum_{i=\text{resonant}} \sum_{l=\text{resonant}} \langle R_{ilil} \rangle \quad (90) \end{aligned}$$

where $\langle \rangle$ indicates frequency averaging over a frequency band centered at f .

Defining the plate radiation factor $\bar{\sigma}$ as the ratio of radiated sound power and the plate velocity squared times the acoustic impedance, one has

$$\begin{aligned} \bar{\sigma} &= \frac{\langle \Pi_{\text{rad}} \rangle}{\rho c \langle V^2 \rangle} \\ &= \frac{\langle \omega^2 |a_{il}|^2 \rangle \sum_{i=\text{resonant}} \sum_{l=\text{resonant}} \langle R_{ilil} \rangle}{\rho c \langle \omega^2 |a_{il}|^2 \rangle \sum_{i=\text{resonant}} \sum_{l=\text{resonant}} N_{il}} \\ &= \frac{1}{N_{\text{res}}} \sum_{i=\text{resonant}} \sum_{l=\text{resonant}} \langle \sigma_{il} \rangle \quad (91) \end{aligned}$$

where N_{res} is the number of resonant modes.

The plate radiation factor $\bar{\sigma}$ has been estimated (see reference 13 and the correction in reference 31), and

Table 2 Radiation Factor $\bar{\sigma}$ for Rectangular Simply Supported Plate of Length a and Width b

$$\begin{aligned} f < f_c & \quad \bar{\sigma} = \frac{2\lambda_a \lambda_c}{ab} \frac{f}{f_c} g_1 + \frac{2(a+b)\lambda_c}{ab} g_2 \\ f \approx f_c & \quad \bar{\sigma} = \sqrt{\frac{a}{\lambda_c}} + \sqrt{\frac{b}{\lambda_c}} \\ f > f_c & \quad \bar{\sigma} = \frac{1}{\sqrt{f_c/f}} \end{aligned}$$

Sources: After Refs. 6 and 31.

analytical expressions obtained are given in Table 2. It permits one to quickly get an approximate value for the radiated sound power from a knowledge of the plate mechanical response. The major phenomenon is the low radiation below the critical frequency of the plate $f_c = c^2 \sqrt{M/D}$, because of the acoustical short circuit, and a radiation factor equal to unity above. The maximum efficiency occurs at the critical frequency. The expressions given in Table 2 are approximations and may differ from those of different authors.

In Table 2, λ is the acoustic wavelength, and λ_c is the acoustic wavelength at the critical frequency. The two coefficients g_1 and g_2 characterize the sound radiation from the corners and the edges of the plate. One has

$$\begin{aligned} g_1 &= \begin{cases} \frac{4(1-2f/f_c)}{\pi^4 \sqrt{f/f_c - f^2/f_c^2}} & \text{when } f < f_c/2 \\ 0 & \text{when } f > f_c/2 \end{cases} \\ g_2 &= \frac{1}{\pi^2} \frac{1-f/f_c}{(1-f/f_c)^{1.5}} \log \left(\frac{1+\sqrt{f/f_c}}{1-\sqrt{f/f_c}} + 2\sqrt{f/f_c} \right) \end{aligned}$$

The influence of boundary conditions on the radiation factor is not negligible. Following the results presented in Fig. 13 and demonstrated in Berry et al.,²² one can conclude that translational and rotational boundary stiffness modify the radiation efficiency. However, the main influence is associated with the translational one. Below the critical frequency the radiation factor of a rectangular plate having free or guided boundary conditions is much smaller than the radiation factor of the same plate simply supported or clamped. This indicates that blocking the translational motion of the plate boundary strongly increases the radiation efficiency. On the other hand, clamped or simply supported plates (resp. guided or free) have approximately the same radiation efficiency, indicating that blocking the rotational motion at the boundaries is not so important. Above the critical frequency the radiation factor tends to unity whatever the boundary conditions of the plate.

6 RESPONSE OF STRUCTURES TO SOUND EXCITATION

6.1 Infinite Plate Excited by a Plane Wave

A basic case to understand the phenomena of structural excitation by field pressure a sound is the infinite plate excited by a plane wave. The advantage of this case

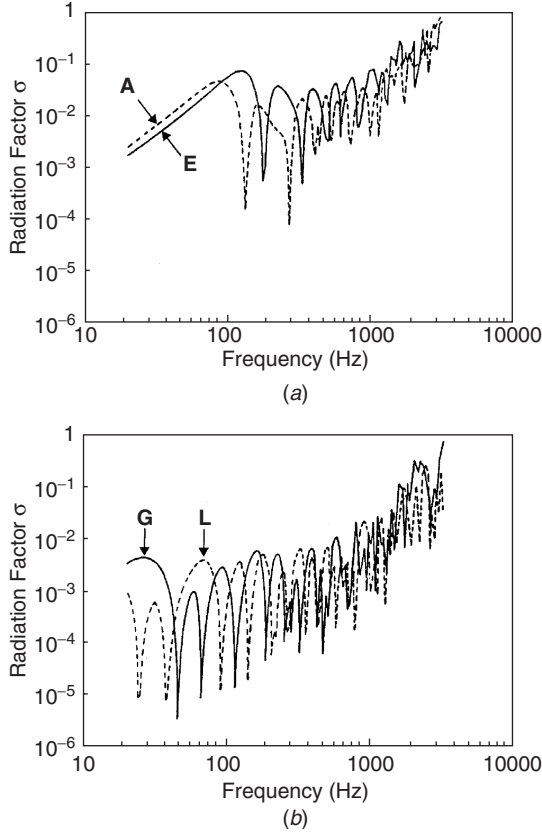

Figure 13 (a) Radiation factor σ of a rectangular plate for different types of boundary conditions. A simply supported, E clamped. (b) Radiation factor of a rectangular plate for different types of boundary conditions. G guided, L free. (From Berry et al.²²)

is the simplicity of the structural response calculation, which permits one to clearly explain the governing mechanisms.

Let us consider an infinite plate separating an acoustic medium into two parts. In the first one a plane incident wave is reflected by the plate, while in the second a plane wave is transmitted.

The sound pressure in the emitting half-space is given by

$$p_1(x, y, z) = \exp[-jk \sin(\theta) \sin(\phi)x - jk \sin(\theta) \cos(\phi)y] \{ \exp[-jk \cos(\theta)z] + B \exp[jk \cos(\theta)z] \} \quad (92)$$

The sound pressure in the receiving half-space is given by

$$p_2(x, y, z) = \exp[-jk \sin(\theta) \sin(\phi)x - jk \sin(\theta) \cos(\phi)y] \times \{ A \exp[-jk \cos(\theta)z] \} \quad (93)$$

The plate displacement has the form

$$W(x, y) = C \exp[-jk \sin(\theta) \sin(\phi)x - jk \sin(\theta) \cos(\phi)y] \quad (94)$$

The verification of velocity continuity of the plate and the acoustic normal velocity and of the plate equation of motion allows us to find the amplitudes of sound pressures and plate waves:

$$C = \frac{2}{\left\{ -\omega^2 M + D(1 + j\eta)[k^4 \sin^4(\theta)] + 2j\omega[\rho c / \cos(\theta)] \right\}} \quad (95)$$

$$B = 1 - j\omega \frac{\rho c}{\cos(\theta)} C \quad (96)$$

$$A = j\omega \frac{\rho c}{\cos(\theta)} C \quad (97)$$

The amplitude C of the plate vibration depends, of course, on its mass and bending stiffness. These effects are quite different and depend on frequency. Figure 14 presents the plate velocity level versus frequency for different angles of incidence.

At the angular coincidence frequency ω_{coi} , the plate amplitude is maximum:

$$C = \frac{2}{M(j\eta)\omega_{coi}^2 + 2j\omega_{coi}[\rho c / \cos(\theta)]} \quad (98)$$

where

$$\omega_{coi} = \frac{c^2}{\sin^2(\theta)} \sqrt{\frac{M}{D}} \quad (99)$$

This maximum plate response is due to the coincidence phenomenon, which appears when the projection of the acoustic wavelength is equal to the plate natural bending wavelength. This situation is only possible at the coincidence frequency. If, in addition, the plate damping loss factor η is equal to zero the plate does not modify the sound propagation. One has $B = 0$ and $A = 1$, which indicates no reflection by the plate.

At low frequency, $\omega < \omega_{coi}$, the plate response is governed by its mass; the plate amplitude of vibration is equal to

$$C \approx \frac{2}{-M\omega^2}$$

At high frequency, $\omega > \omega_{coi}$, the plate response is governed by the stiffness effect; the plate amplitude is equal to

$$C \approx \frac{2}{D[k^4 \sin^4(\theta)]}$$

The presence of the fluid appears like additional damping for the plate. When the plate is in vacuum, the damping effect is associated with the term $D(j\eta)(k^4 \sin^4(\theta))$, and when it is immersed in

Figure 14 Plate velocity level be consistent, L_v , versus frequency (Hz) for three angles of incidence ($\pi/3$, $\pi/4$, $\pi/5$). Steel plate of 0.01 m thickness and damping loss factor equal to 0.01.

the fluid it is associated with $D(j\eta)[k^4 \sin^4(\theta)] + 2j[\rho c / \cos(\theta)]$. Thus, one can define an equivalent plate loss factor η_{eq} including dissipation in the plate and acoustic emission from the plate:

$$\eta_{eq} = \eta + \frac{2[\rho c / \cos(\theta)]}{D[k^4 \sin^4(\theta)]} \quad (100)$$

To summarize, one can say that the level of vibration induced by acoustic excitation is controlled by the mass of the plate below the coincidence frequency. Then the maximum appears with the coincidence effect, and the plate amplitude is limited by damping due to internal dissipation but also to sound re-radiation by the plate (see Fig. 15). At higher frequency the plate velocity level is controlled by the bending stiffness. It decreases with increasing frequency. The coincidence phenomenon appears at the coincidence frequency and depends on the incidence angle; see Fig. 14. Its minimum value is obtained for grazing incidence waves and is equal to the critical frequency as was discussed in Section 5.2 as the frequency limit of radiation from infinite plates. The coincidence frequency tends to infinity for normal incidence, meaning that the coincidence phenomenon does not exist anymore.

The excitation of the infinite plate by a reverberant sound field can be studied by summing the effect of plane waves of different angles of incidence. (see Fig. 16.) The square of the velocity of a plate excited by a sound diffuse field can be calculated adding plate

squared velocities created by each wave of the diffuse field, and the following result can be obtained:

$$\begin{aligned} \int_0^{2\pi} \int_0^{\pi/2} \omega^2 |W(x, y)|^2 d\theta d\phi &= 2\pi \int_0^{\pi/2} |C|^2 d\theta \\ &\int_0^{\pi/2} \{ (8\pi\omega^2) / [1 - \omega^2 M + D[k^4 \sin^4(\theta)]]^2 \\ &+ \{ D\eta[k^4 \sin^4(\theta)] \\ &+ 2\omega[\rho c / \cos(\theta)]^2 \} \} \sin \theta d\theta \end{aligned} \quad (101)$$

For diffuse field excitation the averaging effect does not change the general trends observed for oblique incidence. The maximum of the plate response appears at the critical frequency $\omega_c = c^2 \sqrt{M/D}$, and the peak of maximum velocity is not so sharp as it is for a single angle of incidence.

6.2 Sound Excitation of Finite Baffled Plates

Let us consider a finite rectangular simply supported plate mounted in an infinite rigid baffle, separating the surrounding acoustic medium into two parts, the emitting and receiving half-spaces. An incident plane wave excites the plate, assumed to be and the resulting vibrations produce reflected and transmitted

Figure 15 Plate velocity level, L_v , versus frequency (Hz) for various values of damping loss factor. Steel plate of 0.01 m thickness and angle of incidence of 45° . At the coincidence frequency the curves corresponds from top to bottom to damping loss factors equal to 0.001, 0.021, 0.041, 0.061, 0.081, and 0.101.

Figure 16 Plate velocity level versus frequency (Hz), for diffuse field excitation. Steel plate of 0.01 m thickness with damping loss factor equal to 0.02.

sound waves. Classically, the reflected sound wave is assumed to be decomposed into a reflected plane wave, assuming that the plate is motionless, and a radiated wave due to the plate vibration. The sound pressures in the emitting and receiving half-space, have the following form:

$$p_1(x, y, z) = p_1^{\text{blocked}}(x, y, z) + p_1^{\text{rad}}(x, y, z) \quad (102)$$

$$p_2(x, y, z) = p_2^{\text{rad}}(x, y, z) \quad (103)$$

where the blocked and radiated sound pressures are given by Eqs. (104) and (105), respectively. The blocked sound pressure is the superposition of incident and reflected plane waves when the plate is

motionless:

$$p_1^{\text{blocked}}(x, y, z) = \exp(-jk \sin \theta \sin \phi x - jk \sin \theta \cos \phi y) [\exp(-jk \cos \theta z) + \exp(jk \cos \theta z)] \quad (104)$$

The expression for the radiated sound pressure has been derived in Section 4, taking into account the modal expansion of the plate response:

$$p_m^{\text{rad}}(x, y, z) = \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} j \omega \rho a_{il} \times \int_0^a \int_0^b f_{il}(x_0, y_0) g_R^m(x_0, y_0, 0; x, y, z) \times dx dy, \quad m = 1, 2 \quad (105)$$

To calculate sound pressure fields one has to solve the plate equation of motion:

$$-\omega^2 MW(x, y) + D \left(\frac{\partial^4 W}{\partial x^4} + 2 \frac{\partial^4 W}{\partial x^2 \partial y^2} + \frac{\partial^4 W}{\partial y^4} \right) \times (x, y) = p_1(x, y, 0) - p_2(x, y, 0) \quad (106)$$

The solution of this equation is obtained by modal decomposition, with resonance frequencies ω_{il} and mode shapes $f_{il}(x, y)$ given by

$$\omega_{il} = \sqrt{\frac{D}{M}} \left[\left(\frac{i\pi}{a} \right)^2 + \left(\frac{l\pi}{b} \right)^2 \right],$$

$$f_{il}(x, y) = \sin \left(\frac{i\pi}{a} x \right) \sin \left(\frac{l\pi}{b} y \right) \quad (107)$$

where D is the bending stiffness and M is the mass per unit area of the plate, a is the width and b is the length.

The plate response is calculated by expanding it in its in vacuo plate modes.

$$W(x, y) = \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} a_{il} f_{il}(x, y) = \sum_{i=1}^{\infty} \sum_{l=1}^{\infty} a_{il} \sin \left(\frac{i\pi}{a} x \right) \times \sin \left(\frac{l\pi}{b} y \right) \quad (108)$$

After substitution of the modal expansion into the plate equation of motion and use of orthogonality properties, the modal amplitudes are found to satisfy Eq. (109):

$$\begin{aligned}
& -\omega^2 M_{nm} a_{nm} + K_{nm} (1 + j\eta) a_{nm} \\
& = P_{nm} - \sum_{r=1}^{\infty} \sum_{s=1}^{\infty} j \omega a_{nm} (Z_{nmrs}^1 + Z_{nmrs}^2) N_{nm} \quad (109)
\end{aligned}$$

where a_{nm} is the plate mode (n, m) amplitude, M_{nm} is the generalized mass, K_{nm} is the generalized stiffness of mode (n, m) and η the damping loss factor of the plate.

In the right hand side of the equation, two terms appear. The first one

$$\begin{aligned}
P_{nm} &= \int_0^a \int_0^b p_1^{\text{blocked}}(x, y, 0) \\
&\quad \times \sin\left(\frac{n\pi}{a}x\right) \sin\left(\frac{m\pi}{b}y\right) dx dy \quad (110)
\end{aligned}$$

is the generalized force due to the acoustic excitation. The second represents the influence of the plate radiation on the response. It can be calculated as in Section 5.1. The term is characterized by modal responses of two modes (n, m) and (r, s) and

$$\begin{aligned}
Z_{nmrs}^i &= \frac{1}{N_{rs}} \int_0^a \int_0^b \int_0^a \int_0^b \sin\left(\frac{n\pi}{a}x\right) \sin\left(\frac{m\pi}{b}y\right) \\
&\quad \times g_R^i(x, y, 0; x_0, y_0, 0) \sin\left(\frac{r\pi}{a}x_0\right) \\
&\quad \times \sin\left(\frac{s\pi}{b}y_0\right) dx dy dx_0 dy_0 \quad (111)
\end{aligned}$$

their radiation impedance in the fluid medium i .

A first conclusion that can be drawn concerning the influence of the fluid surrounding the plate is the coupling of in vacuum modes through the radiation impedances. For heavy fluids like water this coupling cannot be ignored, and in vacuum resonance frequencies and mode shapes are completely different when the plate is fluid loaded. On the other hand for light fluids the structural behavior is not strongly modified by fluid loading, and the modal response can be approximated by neglecting modal cross coupling.

$$\begin{aligned}
& -\omega^2 M_{nm} a_{nm} + K_{nm} (1 + j\eta) a_{nm} \\
& = P_{nm} - j \omega a_{nm} (Z_{nmnm}^1 + Z_{nmnm}^2) N_{nm} \quad (112)
\end{aligned}$$

The radiation impedance of mode (n, m) is a complex quantity, so one can separate modal resistance and reactance into real and imaginary part, respectively:

$$Z_{nmnm}^i = R_{nmnm}^i + j X_{nmnm}^i$$

The amplitude of mode (n, m) is then governed by the following equation :

$$\begin{aligned}
& -\omega^2 [M_{nm} + (X_{nmnm}^1 + X_{nmnm}^2)/\omega N_{nm}] a_{nm} \\
& + K_{nm} \{1 + j(\eta + [R_{nmnm}^1 + R_{nmnm}^2]/K_{nm}) \\
& \times \omega N_{nm}\} a_{nm} = P_{nm} \quad (113)
\end{aligned}$$

Physically, one can see that radiation reactances produce an effect of added modal mass, and the resonance frequencies of panels tend to decrease when they are fluid loaded. The radiation resistances introduce an additional damping compared to the in vacuo situation. In fact, the additional losses of one plate mode are equal to the power it radiates into both fluid media.

In the case of an infinite plate, the fluid loading introduces only additional damping and no additional mass on the plate. This is due to the type of sound wave created: Only propagating waves exist for infinite plates compared to the finite plate vibration case which produces both propagating and evanescent waves. Propagating waves are responsible for additional damping; evanescent waves are responsible for additional mass.

The generalized force takes into account the excitation of plate modes by the blocked pressure:

$$\begin{aligned}
P_{nm} &= 2 \int_0^a \int_0^b \exp[-jk \sin(\theta) \sin(\phi)x] \\
&\quad \times -jk \sin(\theta) \cos(\phi)y] \sin\left(\frac{n\pi}{a}x\right) \\
&\quad \times \sin\left(\frac{m\pi}{b}y\right) dx dy \quad (114)
\end{aligned}$$

The calculation of the generalized force shows the important phenomenon of joint acceptance. After calculation one has

$$\begin{aligned}
P_{nm} &= \frac{64 \left(\frac{n\pi}{a}\right)^2 \left(\frac{m\pi}{b}\right)^2}{\left\{ \left[(k \sin \theta \sin \phi)^2 - \left(\frac{n\pi}{a}\right)^2 \right]^2 \right.} \\
&\quad \times \left. \left[(k \sin \theta \cos \phi)^2 - \left(\frac{m\pi}{b}\right)^2 \right]^2 \right\}} \\
&\quad \times \left\{ \begin{aligned} & \cos^2 \left(k \sin \theta \sin \phi \frac{a}{2} \right) \\ & \times \cos^2 \left(k \sin \theta \cos \phi \frac{b}{2} \right) \\ & \cos^2 \left(k \sin \theta \sin \phi \frac{a}{2} \right) \\ & \times \sin^2 \left(k \sin \theta \cos \phi \frac{b}{2} \right) \\ & \sin^2 \left(k \sin \theta \sin \phi \frac{a}{2} \right) \\ & \times \cos^2 \left(k \sin \theta \cos \phi \frac{b}{2} \right) \\ & \sin^2 \left(k \sin \theta \sin \phi \frac{a}{2} \right) \\ & \times \sin^2 \left(k \sin \theta \cos \phi \frac{b}{2} \right) \end{aligned} \right\} \quad (115)
\end{aligned}$$

In Eq. (115), four cases are possible: from top to bottom they corresponds to (odd, odd), (odd, even), (even, odd), and (even, even) modes.

Because of the singularity of the denominator in Eq. (115), one can see that modes satisfying Eqs. (116) and (117) are highly excited; their joint acceptances are large:

$$\omega = \left(\frac{n\pi}{a}\right) \frac{c}{\sin \theta \sin \phi} \quad (116)$$

$$\omega = \left(\frac{m\pi}{b}\right) \frac{c}{\sin \theta \cos \phi} \quad (117)$$

However, a high level of excitation is not sufficient to produce a high level of response of the mode. It is also necessary to excite it at its resonance frequency, and thus to satisfy Eq. (118).

$$\omega = \omega_{nm} = \sqrt{\frac{D}{M}} \left[\left(\frac{n\pi}{a}\right)^2 + \left(\frac{m\pi}{b}\right)^2 \right] \quad (118)$$

The fulfilment of these three conditions is only possible at one frequency, the coincidence frequency:

$$\omega_{\text{coin}} = \sqrt{\frac{M}{D}} \frac{c^2}{(\sin \theta)^2} \quad (119)$$

For infinite plates the coincidence frequency already exists and is characterized by a high amplitude of vibration due to the coincidence of the acoustics and plate natural wavenumbers. For finite plates a second interpretation of the same phenomenon can be made, the high level of vibration being due to resonant modes having maximum joint acceptance values.

7 CONCLUSIONS

In this section the basic phenomenon of sound radiation from structures has been presented on the case of plates. Of course, more complicated structures have specific behavior, but the major trends remain close to plates. In particular an acoustic short circuit appears for frequencies below the critical frequency, and the radiation efficiency is low, meaning that structural vibrations have difficulty to produce noise. Modal decomposition and wave decomposition of the vibration fields have been used to describe the radiation phenomenon leading to concepts of radiating and nonradiating waves or modal radiation efficiency. The influence of structural boundary conditions is important below the critical frequency. However, blocking the translational motion has a stronger influence than blocking the rotational motion.

The classical approach to predict sound radiation is based on integral equations. The method has been described here and different possibilities presented based on Kirchhoff or Rayleigh integrals. A second possibility is presented that consists of replacing the structure by equivalent acoustic sources located inside the volume that is occupied by the structure and which produce the same vibration field.

Finally, the excitation of structures by a sound field has been presented. The major tendency that appears is the reciprocity of the radiation of sound from structures and the structural response excited by sound. Many studies have been made during the past three decades and numerical tools have been developed for prediction of radiated sound pressure by industrial structures. The remaining problems are associated with time-consuming calculations and dispersion of experimental results. This leads the research in this field toward energy methods and frequency averaging to predict the sound radiation from structures. These new trends can be found in the literature.³⁷⁻⁴¹

CHAPTER 7

NUMERICAL ACOUSTICAL MODELING (FINITE ELEMENT MODELING)

R. Jeremy Astley
Institute of Sound and Vibration Research
University of Southampton
Southampton, United Kingdom

1 INTRODUCTION

The finite element (FE) method has become a practical technique for acoustical analysis and solution of noise and vibration problems. In recent years, the method has become relatively accessible to practicing engineers and acousticians through specialized acoustical codes or as an adjunct to larger general-purpose FE programs. The intention here is not to educate the reader in programming the finite element method for acoustics but rather to present the essential features of the method and to indicate the types of analysis for which it can be used. The accuracy and limitations that may be expected from current models will also be discussed. More advanced FE formulations, which are the subject of research rather than industrial application, will also be reviewed.

2 FINITE ELEMENT METHOD

The finite element method emerged in the early 1960s as one of several computer-based techniques competing to replace traditional analytic and graphical methods of structural analysis. It rapidly achieved a position of dominance and spread to other branches of continuum mechanics and engineering physics.

The first indication that the FE approach could be applied to acoustics came with pioneering work by Gladwell, Craggs, Kagawa, and others in the late 1960s and early 1970s.¹ The boundary element (BE) technique was also being developed at this time, and the first commercial computer code to focus specifically on acoustics and vibration embodied both methods.* The further development of specialized codes for acoustics† and the inclusion of more extensive acoustical capabilities in general-purpose FE codes‡ has continued to the present day.

Accurate prediction of noise has become increasingly important in many areas of engineering design as environmental considerations play a larger role in defining the public acceptance and commercial viability of new technologies. In the aircraft and automotive industries, for example, acceptable levels of interior noise and exterior community noise are critical factors in determining the viability of new engine and airframe

concepts. The need for precise acoustical predictions for such applications acts as a driving force for current developments in BE and FE methods for acoustics.

The question of whether BE or FE methods are the more effective for acoustical computations remains an open one. BE models that discretize only the bounding surface require fewer degrees of freedom but are nonlocal in space. FE models require many more variables but are local in space and time, which greatly reduces the solution time for the resulting equations.² In the case of homogeneous, uncoupled problems, it is generally true that BE methods produce a faster solution; certainly this is the case for “fast multipole” BE methods,³ which are currently unassailable as regards efficiency for scattering computations in homogeneous media. The strength of FE models lies in their general robustness and in their ability to treat inhomogeneous media and to take advantage of the sparse nature of structural discrete models in coupled acoustical-structural computations.⁴

3 AN ACOUSTICAL FE MODEL

The FE method is “domain-based”.[§] It is based on the notion of polynomial interpolation of acoustic pressure over small but finite subregions of an acoustical domain. A typical^{||} FE acoustical model is illustrated in Fig. 1. This shows a three-dimensional FE model for an acoustical muffler of fairly complex geometry.^{||} The FE *mesh* is formed by dividing the interior of the muffler into a large number of nonoverlapping *elements*. These are subregions of finite extent, in this case tetrahedra. A finite number of *nodes* define the topology of each element. These are placed on the vertices, edges, or surfaces of the element or at interior points. In the current instance, the nodes are placed at the four vertices of the tetrahedron. The FE method facilitates the use of an *unstructured*

*SYSNOISE, released by Dynamic Engineering in 1988.

†For example, SYSNOISE, ACTRAN, and COMET.

‡For example, MSC/NASTRAN, ANSYS, and ABAQUS.

[§]It is based on a discrete model for the entire solution domain. It differs in this regard from the Boundary Element Method (BEM) which involves a discretization only of the bounding surfaces of the region.

^{||}The model is “typical” in that it represents the sort of acoustical problem that can be treated in a routine fashion by commercially available FE acoustical codes.

^{||}Courtesy of Free Field Technologies S. A. (FFT). The mesh shown was used for an acoustical study using MSC-Actran.

Figure 1 Acoustical finite element mesh and topology of a single element (enlarged).

mesh, in that elements can vary arbitrarily in size and position provided that contiguous elements are joined node for node in a “compatible” way. This in turn facilitates automatic mesh generation for arbitrarily shaped domains, an important practical consideration. The FE model differs in this regard from low-dispersion finite difference (FD) schemes,⁵ which have also been applied to acoustical problems but which rely upon a “structured” mesh in which grid points are aligned in regular rows or planes.*

In the FE formulation, the acoustic pressures at each node— p_j , say, at node j —become the *degrees of freedom* of a discrete model. For problems of linear acoustics, the resulting equations are linear in the unknown nodal pressures. They must then be solved at each instant in time in the case of a transient solution or for each frequency of interest in the case of time harmonic excitation. The approximate FE solution exists not just at the nodes but at all points throughout the elements. The nature of the interpolation used within an element is central to the FE concept. It leads to the notion of *shape functions*, which define the variation of the dependent variable in terms of nodal values. The ability of the mesh to accurately represent the physical solution depends upon the complexity of the shape functions and the size of the elements. Central to estimates of accuracy in acoustical problems is the relationship between the node spacing and the characteristic wavelength of the solution, often characterized as a target figure for “nodes per wavelength.”

The following types of analysis can be performed by current FE acoustical codes, some more routinely than others:

- Calculation of the natural frequencies and eigenmodes of acoustical enclosures
- Calculation of the response of interior acoustic volumes to structural excitation and/or distributed acoustic sources

- Coupled acoustical-structural analysis of types 1 and 2
- Propagation through porous media and absorption by acoustically treated surfaces
- Radiation and scattering in unbounded domains
- Transmission in ducts and waveguides
- The analysis of acoustic propagation on mean flows

Not *all* of these capabilities are available in *all* program. Indeed, they have been listed roughly in order of increasing complexity. The first two or three will be found in many general-purpose, predominantly structural FE codes while the remainder are progressively the preserve of codes that specialize in acoustics and vibration. Most of these analyses are performed in the frequency domain.

The remainder of this chapter is organized in the following way. The field equations and boundary conditions of linear acoustics are introduced in Section 4. A derivation of the discrete FE equations is given in Section 5, followed by a discussion of the types of discrete analysis that can then be performed. Element interpolation and its impact on accuracy and convergence are detailed in Section 6. Applications to ducts and waveguides are dealt with in Section 7, and the use of FE models for unbounded problems is covered in Section 8. FE models for flow acoustics are discussed in Section 9. The particular issues involved in the solution of very large sets of FE equations are reviewed in Section 10, along with current attempts to reduce problem size by using functions other than polynomials as a basis for FE models. Some general comments follow in Section 11.

4 EQUATIONS OF ACOUSTICS

4.1 Acoustic Wave Equation and the Helmholtz Equation

The acoustic pressure $P(\mathbf{x}, t)$ at location \mathbf{x} and time t in a quiescent, compressible, lossless medium is governed by the linearized wave equation

$$\rho_0 \nabla \cdot \left(\frac{1}{\rho_0} \nabla P \right) - \frac{1}{c_0^2} \frac{\partial^2 P}{\partial t^2} = S(\mathbf{x}, t) \quad (1)$$

where $\rho_0(\mathbf{x})$ and $c_0(\mathbf{x})$ are the local density and sound speed, and $S(\mathbf{x}, t)$ is a distributed acoustic source[†]. The corresponding acoustic velocity $\mathbf{U}(\mathbf{x}, t)$ is related to the acoustic pressure by the linearized inviscid momentum equation

$$\frac{\partial \mathbf{U}}{\partial t} = -\frac{1}{\rho_0} \nabla P \quad (2)$$

In the case of time harmonic disturbances of radian frequency ω , for which $P(\mathbf{x}, t) = p(\mathbf{x})e^{i\omega t}$, the resulting

*There are greater similarities between finite element and finite volume schemes, see subsequent comments in Section 9.2.

[†]Often expressed in terms of monopole, dipole, and quadrupole components.

complex pressure amplitudes p and velocity amplitude \mathbf{u}^* satisfy

$$\rho_0 \nabla \cdot \left(\frac{1}{\rho_0} \nabla p \right) + k^2 p = s \quad \text{where} \quad i\omega \mathbf{u} = -\frac{1}{\rho_0} \nabla p \quad (3)$$

where k is the characteristic wavenumber ($= \omega/c_0$). Equation (1) or (3) form the starting point for most FE acoustical models. If the acoustic medium is homogeneous (ρ_0, c_0 constant) Eq. (3) reduces to the standard Helmholtz equation.

4.2 Acoustical Boundary Conditions

Acoustical boundary conditions applied on a bounding surface Γ with a unit outward normal $\hat{\mathbf{n}}$ include the following “standard” cases:

A Rigid Impervious Boundary The normal component of the acoustic velocity is zero on such a boundary. From Eq. (2) this gives

$$\nabla P \cdot \hat{\mathbf{n}} = 0 \quad \text{or} \quad \nabla p \cdot \hat{\mathbf{n}} = 0 \quad (4)$$

A Locally Reacting Boundary (Frequency Domain) The performance of a locally reacting acoustical surface is characterized by a frequency-dependent normal impedance $z(\omega)$, such that $p(\omega) = z(\omega)u_n(\omega)$ where $u_n = \mathbf{u} \cdot \hat{\mathbf{n}}$. By using the second of equations (3) this can be written as a “Robin” boundary condition on acoustic pressure, that is,

$$\nabla p \cdot \hat{\mathbf{n}} = -ikA(\omega)p \quad (5)$$

where $A(\omega)$ is the nondimensional admittance [$= \rho_0 c_0 / z(\omega)$]. A zero admittance corresponds to rigid impervious boundary [cf. (5) and (4)].

A Locally Reacting Boundary (Time Domain). A locally reacting boundary in the time domain is more difficult to define. The inverse Fourier transform of the frequency-domain impedance relationship, $p(\omega) = z(\omega)u_n(\omega)$, gives a convolution integral

$$P(t) = \int_{-\infty}^{+\infty} Z(\tau)U_n(t - \tau) d\tau \quad (6)$$

where $Z(t)$ is the inverse Fourier transform of $z(\omega)$. Equation (6) is difficult to implement in practice since it requires the time history of $U_n(t)$ to be retained for all subsequent times. Also, the form of $z(\omega)$ must be such that $Z(t)$ exists and is causal, which is not necessarily the case for impedance models defined empirically in the frequency domain.

*In the remainder of this chapter, time-domain quantities are denoted by upper-case variables $P, U, S \dots$ and corresponding frequency-domain quantities by lower case variables p, u, s, \dots .

A time-domain impedance condition based on expression (6) but suitable for FE implementation has been proposed by Van den Nieuwenhof and Coyette.⁶ It gives stable and accurate solutions provided that the impedance can be approximated by a rational expression

$$\frac{z(\omega)}{\rho_0 c_0} = r_1 + \frac{r_2 - r_1}{1 + i\omega r_3} + \frac{i\omega r_4}{1 + i\omega r_5 - \omega^2 / r_6^2} + i\omega r_7 \quad (7)$$

where the constants r_1, \dots, r_7 must satisfy stability constraints. Alternatively, and this has only been implemented in finite difference (FD) models to date rather than FE models, one-dimensional elements can be attached to the impedance surface to explicitly represent the effect of cavity liners.⁷

A Prescribed Normal Displacement If the bounding surface experiences a prescribed, structural displacement, continuity of normal acceleration at the surface gives

$$\nabla P \cdot \hat{\mathbf{n}} = \rho_0 \ddot{W} \quad \text{or} \quad \nabla p \cdot \hat{\mathbf{n}} = -\omega^2 \rho_0 w \quad (8)$$

where $W(\mathbf{x}, t) = w(\mathbf{x})e^{i\omega t}$ is the normal displacement into the acoustical domain.

The Sommerfeld Radiation Condition At a large but finite radius R from an acoustical source or scattering surface, an unbounded solution of the Helmholtz equation must contain only outwardly propagating components. This constraint must be included in any mathematical statement of the problem for unbounded domains. The Sommerfeld condition, that

$$\frac{\partial p}{\partial r} + ikp = o(R^{-\alpha}), \quad (9)$$

ensures that this is the case where $\alpha = \frac{1}{2}$ or 1 for two-dimensional (2D) and three-dimensional (3D) problems, respectively.

The Sommerfeld condition can be approximated on a distant but finite cylinder (2D) or sphere (3D) by specifying a ρc impedance—or unit nondimensional admittance $A(\omega) = 1$. This is a *plane damper*, which is transparent to plane waves propagating normal to the boundary. More accurate *spherical* and *cylindrical* dampers, transparent to cylindrical and spherically symmetric waves, are obtained by setting $A(\omega)$ equal to $(ik + R^{-1})$ and $(ik + \frac{1}{2}R^{-1/2})$, respectively.

Higher order nonreflecting boundary conditions (NRBCs), which can be applied closer to the scattering surface, have also been derived. Many involve higher order radial derivatives, which are difficult to accommodate in a weak Helmholtz sense. The second-order NRBC proposed by Bayliss, Gunzberger, and Turkel⁸ is, however, widely used and can be imposed weakly by replacing the admittance $A(\omega)$ of Eq. (5) by a differential operator involving only first-order radial derivatives.

Many *nonlocal* approximations for the far-field boundary have also been developed but are generally less attractive for FE implementation. These include the DtN approach of Givoli and Keller, mode matching, and coupling to boundary integral schemes. A general review of these methods is found in Givoli's monograph.⁹

5 GENERAL FINITE ELEMENT FORMULATION FOR INTERIOR PROBLEMS

Consider an acoustical region Ω bounded by a surface Γ . Such an arrangement is illustrated in two dimensions in Fig. 2. The bounding surface Γ is divided into nonoverlapping segments that correspond to an acoustically *hard* segment (Γ_h), a locally reacting *soft* segment (Γ_z), and a *structural* boundary (Γ_{st}) on which a normal displacement w is prescribed. These are modeled by boundary conditions (4), (5), and (8). The solution domain Ω is divided into a discrete number of finite elements. In Fig. 2 these take the form of two-dimensional triangles defined by corner nodes. Many other element topologies are possible (see Section 6).

5.1 Trial Solution and Shape Functions

The acoustic pressure $P(\mathbf{x}, t)$ —or the acoustic pressure amplitude $p(\mathbf{x}, \omega)$ in the time-harmonic case—are approximated by trial solutions \tilde{P} or \tilde{p} of the form

$$\begin{aligned}\tilde{P}(\mathbf{x}, t) &= \sum_{j=1}^n P_j(t) N_j(\mathbf{x}) \quad \text{and} \\ \tilde{p}(\mathbf{x}, \omega) &= \sum_{j=1}^n p_j(\omega) N_j(\mathbf{x})\end{aligned}\quad (10)$$

where P_j or p_j denotes nodal values of pressure or pressure amplitude at node j , and n is the total number of nodes. The function $N_j(\mathbf{x})$ is termed a *shape function*. It takes the value of unity at node j and zero at all other nodes.* The shape functions act globally as interpolation functions for the trial solution but are defined locally within each element as polynomials in physical or mapped spatial coordinates. For example, the shape functions of the triangular elements shown in Fig. 2a are formed from the basis set $\{1, x, y\}$. Within each triangle they take the form $(a_1 + a_2x + a_3y)$ where a_1 , a_2 , and a_3 are constants chosen so that the trial solution within the element takes the correct value at each node. This means that the number of polynomial terms in the basis set must be the same as the number of nodes in the element topology (three in this case).

The element shape functions defined in this way combine to form a global shape function $N_j(\mathbf{x})$ that itself takes a value of unity at node j and zero at all other nodes. This is indicated by the “hat shaped” function in Fig. 2b. The trial solution itself, which is given by expression (10), is then a summation of these functions weighted by the nodal values of pressure. In the case of the model illustrated in Fig. 2, this gives a trial solution that can be visualized as a piecewise continuous assembly of plane facets when plotted as a surface over the x - y plane, as shown in Fig. 2c. Although the notion of a global trial solution and of global shape functions are useful in a conceptual sense, all of the operations required to form the finite element equations are performed at the element level.

*This is not strictly true in the case of hierarchical elements where shape functions are associated with edges or faces rather than with nodes.

Figure 2 The FE model. (a) Geometry, mesh, and boundary conditions. (b) Global shape function $N_j(\mathbf{x})$. (c) Trial solution.

A definition of the shape functions within each element is therefore all that is needed in practice.

5.2 Weak Variational Formulation

Consider the problem posed by Eq. (3) subject to boundary conditions (4), (5), and (8). By multiplying Eq. (3) by a test function $f(\mathbf{x})$, integrating over Ω and applying the divergence theorem, we obtain an equivalent integral statement that

$$\begin{aligned} \int_{\Omega} \frac{1}{\rho_0} [\nabla f \cdot \nabla \tilde{p} - \frac{\omega^2}{c_0^2} f \tilde{p}] d\Omega + i\omega \int_{\Gamma_z} \frac{A(\omega)}{\rho_0 c_0} f \tilde{p} d\Gamma \\ + \int_{\Gamma_{st}} \omega^2 f w_n d\Gamma + \int_{\Omega} \frac{1}{\rho_0} f s d\Omega = 0 \end{aligned} \quad (11)$$

where f is continuous and differentiable.* The second and third terms in the above expression are obtained by assuming that the normal derivatives of pressure on Γ_z and Γ_{st} satisfy Eqs. (5) and (8). This integral statement therefore embodies a *weak* expression of these boundary conditions. Note also that when the admittance is zero, the integral over Γ_z disappears, so that the default *natural* boundary condition on an external surface—if no other condition is specified—is that of a hard acoustical surface.

5.3 Discrete Equations

When the trial solution of expression (10) is substituted into the integral relationship (11), a linear equation is obtained in the unknown coefficients $p_j(\omega)$. By using a complete set of test functions, f_k say ($k = 1, 2, \dots, n$), a complete set of linear equations is generated. This requires the selection of suitable test functions that satisfy appropriate continuity requirements. The shape functions $N_j(x)$ are a natural choice. By setting $f_k(\mathbf{x}) = N_k(\mathbf{x})$, ($k = 1, \dots, n$), we obtain a symmetric system of linear equations:

$$[\mathbf{K} + i\omega\mathbf{C} - \omega^2\mathbf{M}]\{\mathbf{p}\} = \{\mathbf{f}_{st}\} + \{\mathbf{f}_s\} \quad (12)$$

where \mathbf{M} , \mathbf{K} , and \mathbf{C} are acoustic *mass*, *stiffness*, and *damping* matrices given by

$$\begin{aligned} M_{jk} &= \int_{\Omega} \frac{N_j N_k}{\rho_0 c_0^2} d\Omega, & K_{jk} &= \int_{\Omega} \frac{\nabla N_j \cdot \nabla N_k}{\rho_0} d\Omega, \\ C_{jk} &= \int_{\Gamma_z} \frac{A(\omega)}{\rho_0 c_0} N_j N_k d\Gamma \end{aligned} \quad (13)$$

and the vectors $\{\mathbf{f}_{st}\}$ and $\{\mathbf{f}_s\}$ are forcing terms due to structural excitation and acoustic sources. They are given by

$$\begin{aligned} \{f_{st}\}_j &= - \int_{\Gamma_w} \omega^2 N_j w_n d\Gamma \quad \text{and} \\ \{f_s\}_j &= - \int_{\Omega} \frac{1}{\rho_0} N_j s d\Omega \end{aligned} \quad (14)$$

The above integrals are evaluated element by element and *assembled* to form the global matrices \mathbf{K} , \mathbf{C} , and \mathbf{M} and the forcing vectors \mathbf{f}_s and \mathbf{f}_{st} . The *assembly* procedure is common to all FE models and is described elsewhere.¹⁰ Numerical integration is generally used within each element.

5.4 Types of Analysis

Frequency Response The solution of Eq. (12) over a range of frequencies gives the forced acoustical response of the system. The presence of bulk absorbing materials within such a system is accommodated quite easily since continuity of normal particle velocity is weakly enforced at any discontinuity of material properties within Ω . Inhomogeneous reactive regions within the finite element model are, therefore, treated by using different material properties— c_0 and ρ_0 —within different elements. Absorptive materials can be modeled in the same way by using complex values of sound speed and density. Empirical models for rigid-porous materials that express c_0 and ρ_0 in terms of a nondimensional parameter $(\sigma/\rho_0 f)$ where σ is the flow resistivity and f the frequency¹¹ are commonly used. Elastic-porous materials can also be modeled, but here additional FE equations for the displacement of the elastic frame must be used to supplement the acoustic equations.^{12,13}

Normal Mode Analysis When the forcing term is removed from Eq. (12) and if no absorption is present, the undamped acoustic modes of the enclosure are solutions of the eigenvalue problem:

$$[\mathbf{K} - \omega^2\mathbf{M}]\{\mathbf{p}\} = 0 \quad (15)$$

The eigenmodes obtained in this way are useful in characterizing the system but can also be used as a reduced basis with which to calculate its frequency response using Eq. (12), as in analogous structural models.¹⁰

Acousto-structural Coupling Structural coupling can be included by supplementing Eq. (12) with an equivalent set of FE equations for the structural displacement on Γ_{st} . This allows the effect of the acoustical loading on the structure to be modelled and *vice versa*. If the trial solution of the structural FE model is analogous to expression (10), but with

*More formally, $f \in H^1(\Omega)$ where $H^1(\Omega) = \{q: \int_{\Omega} [|\nabla q|^2 + |q|^2] d\Omega < \infty\}$.

nodal displacements w_j ($j = 1, 2, \dots, n_{st}$) as degrees of freedom, a coupled system of equations results of the form

$$\begin{bmatrix} \mathbf{K} & \mathbf{0} \\ -\mathbf{A}^T & \mathbf{K}_{st} \end{bmatrix} + i\omega \begin{bmatrix} \mathbf{C} & \mathbf{0} \\ \mathbf{0} & \mathbf{C}_{st} \end{bmatrix} - \omega^2 \begin{bmatrix} \mathbf{M} & -\rho\mathbf{A} \\ \mathbf{0} & \mathbf{M}_{st} \end{bmatrix} \begin{bmatrix} \mathbf{p} \\ \mathbf{w} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_s \\ \mathbf{f}_{ext} \end{bmatrix} \quad (16)$$

where \mathbf{K}_{st} , \mathbf{C}_{st} , and \mathbf{M}_{st} are stiffness, damping, and mass matrices for the structure, and \mathbf{A} is a coupling matrix that contains integral products of the acoustical and structural shape functions over Γ_{st} . The vector \mathbf{f}_{ext} contains external nodal forces and moments applied to the structure. The unsymmetric nature of the coupled mass and stiffness matrices can be inconvenient. If so, Eq. (16) can be symmetrized. This is most simply achieved by using the velocity potential rather than the pressure to describe the acoustic field, but other methods are also used.¹⁴

Transient Response Provided that the acoustic damping matrix is frequency independent, the inverse Fourier transform of Eq. (12) yields an equivalent set of transient equations:

$$[\mathbf{K}]\mathbf{P} + [\mathbf{C}]\dot{\mathbf{P}} + [\mathbf{M}]\ddot{\mathbf{P}} = \{\mathbf{F}_{st}\} + \{\mathbf{F}_s\} \quad (17)$$

where \mathbf{F}_{st} and \mathbf{F}_s are obtained from time-domain versions of expressions (14).^{*} The above equations can be integrated in time by using a numerical time-stepping

scheme. Implicit schemes, such as Newmark- β , are favored for their accuracy and stability, but explicit and indirect implicit schemes are used for large problems, being less memory intensive and more suited to parallel implementation.^{15,16} In cases where frequency-dependent acoustic damping is present, the derivation of suitable time-domain equations is less straightforward. When the damping arises from a frequency-dependent local admittance, for example, a suitable transient impedance boundary condition, along the lines of those discussed in Section 4.2, must be incorporated in to the discrete problem. An example of such a treatment is given in Ref. 6.

6 ELEMENT ORDER, ACCURACY, AND CONVERGENCE

6.1 Types of Element

The elements commonly used for acoustical analysis—and indeed for general FE application—are based on polynomial shape functions of physical or mapped coordinates. Some elements of this type are shown in Fig. 3. Triangular and quadrilateral elements for two-dimensional analysis are shown in the first two columns of the figure, and analogous tetrahedral and hexahedral elements for three dimensions are shown in the last two columns. In the case of the 2D quadrilateral and 3D hexahedral elements the shape functions are obtained in terms of mapped coordinates (ζ, η) and (ζ, η, ξ) rather than Cartesian coordinates (x, y, z) . Details of the shape functions for such elements are given in general FE texts¹⁷ and will not be repeated here. In Fig. 3 the appropriate polynomial basis set is indicated under each element. Note that the number of polynomial terms in each case is equal to the number of nodes. It is simple also to

^{*}A similar set of time-domain equations can be obtained from Eq. (16) for the coupled structural-acoustical problem.

Figure 3 Element topologies.

verify that by holding x or y or z (or ζ or η or ξ) constant, the trial solution within each element varies linearly with the other variables for elements in the top row of Fig. 3 and quadratically for those in the bottom row. The polynomial order p of these elements is $p = 1$ and $p = 2$, respectively. Elements of arbitrary polynomial order can be formulated quite easily, but in practice elements of orders $p > 2$ are not common in general-purpose FE codes. The use of p elements of higher order is, however, attractive as a means of combatting pollution error in acoustics (see Section 6.2). High-order *spectral elements*, which substitute orthogonal polynomials for node-based Lagrangian shape functions, are also used. The reader is referred elsewhere¹⁸ for a more complete discussion of such elements.

6.2 Numerical Error

The error present in the FE solution derives from two sources: *approximability* error and *pollution* error. The approximability error is a measure of the *best approximation*, which can be achieved for a given spatial interpolation. The pollution error is associated with the numerical representation of phase or dispersion and depends on the variational statement itself.

Approximability The best approximation that can be achieved by representing a sinusoidal, time-harmonic disturbance by piecewise continuous polynomial interpolation gives a global error that is proportional to $(kh)^p$ where k is the wavenumber, h is the node spacing, and p is the polynomial order of the shape functions. This is the approximability error of the discrete solution.

In terms of the characteristic wavelength λ of a solution, the approximability error decreases as $(\lambda/h)^{-p}$ where λ/h can be interpreted in a physical sense as the number of nodes that are used to model a single wavelength. The error will decrease more rapidly for higher order elements than for lower order ones due to the index p . An absolute lower limit is $\lambda/h = 2$ (2 nodes per wavelength), which corresponds to an alternating sawtooth pattern in the discrete solution at successive nodes. Larger values of λ/h are clearly needed for any reasonable FE representation using polynomial shape functions. A rule of thumb that is often used is *ten nodes per wavelength*. This is adequate at low frequencies when few wavelength variations are present within the computational domain. It should be used with great caution at higher frequencies for reasons that will become apparent shortly.

Pollution Effect The pollution error in the FE solution is significant when the wavelength of the disturbance is small compared to the dimensions of the computational domain. The magnitude of the pollution effect depends on the underpinning variational statement. It is associated with the notion of numerical dispersion. Small phase differences between the exact and computed solution may not contribute significantly to numerical error over a single

wavelength but accumulate over many wavelengths to give a large global error. The pollution error therefore varies not only with the mesh resolution (nodes per wavelength) but also with the absolute value of frequency. The overall global error for a conventional variational FE solution of the type discussed so far takes the form¹⁹

$$\epsilon = C_1(kh)^p + C_2kL(kh)^{2p} \quad (18)$$

where L is a geometric length scale, p is the element order, and C_1 and C_2 are constants. The first term represents the approximability error, the second the pollution effect. This can be appreciable even for modest values of kL . This is illustrated by the data in Table 1, which is obtained for linear ($p = 1$) one-dimensional elements.* The numbers of nodes per wavelength required to achieve a global error ϵ^\dagger of less than 10% are tabulated for increasing values of kL . In multidimensional situations the pollution effect is further complicated by considerations of element orientation with respect to wave direction.²⁰

Given the form of expression (18), the accuracy of a solution at a given frequency can be improved either by refining the mesh and reducing h for a fixed value of p (h refinement) or by retaining the same mesh and increasing the order of the elements (p refinement) or by some selective application of both techniques (h - p refinement).¹⁸ h refinement remains the most common approach in acoustical applications, although the use of second-order elements rather than linear or bilinear ones is widely recognized as being worthwhile if they are available. Higher order *spectral* elements (typically $p \sim 5$) have, however, been shown to be effective for short-wave problems,²¹ and high-order elements of this type ($p \sim 10 - 15$) have been used in transient FE modeling of seismic wave propagation.²² A difficulty encountered in using very high order elements is that the conditioning of the equations deteriorates as the order increases, particularly when Lagrangian shape functions are used. This is reduced by the use of orthogonal polynomials as shape functions, but the degrees of freedom then relate to edges or faces rather than nodes (for details see Ref. 18). More radical methods for combatting pollution error by using nonpolynomial interpolation will be discussed in Section 10.3.

7 DUCTS AND WAVEGUIDES

7.1 Transmission in Nonuniform Ducts

FE models for transmission in nonuniform ducts differ from those for general interior problems only in their treatment of boundary conditions at the inlet and outlet planes. Often it is possible to neglect higher order modes at the inlet and outlet, and in such cases the most straightforward approach is to use the *four-pole* method proposed by Young and Crocker.²³ This characterizes the transmission properties of an arbitrary duct by means of a transfer matrix that relates arbitrary inlet values of pressure and volume velocity, P_1 and U_1 , to equivalent outlet values, P_2 and U_2 (see Fig. 4). The four terms in the transfer matrix are obtained by solving an FE problem for two

Figure 4 Characterization of acoustical transmission in a nonuniform duct.

different combinations of inlet and outlet parameters. This method can also be applied to systems with mean flow²⁴ and to more complex branched systems by combining transfer matrices for individual components arranged either in series or in parallel.²⁵ A modification proposed by Craggs permits the behavior of a limited number of higher order modes to be modeled in a similar way.²⁶

Such models do not, however, deal accurately with systems where an incident mode is scattered into multiple higher order modes by nonuniform geometry or the presence of liners. Modal boundary conditions should then be used. These involve matching the FE solution at the inlet and outlet planes to truncated series of positively and negatively propagating modes. This yields a set of equations that contains both nodal values of pressure within the duct and modal coefficients at the end planes as unknown variables. The solution of these equations gives a transmission matrix **B** —see Fig. 4 —that relates vectors of the modal coefficients at the inlet (**a**⁺ and **a**[−]) to those at the outlet (**b**⁺ and **b**[−]). Such models have been used extensively for propagation in turbofan inlet and bypass ducts where many modes are generally cut-on.²⁷ A solution for propagation in a lined axisymmetric bypass duct is shown in Fig. 5.²⁸ The power in each cut-on mode is plotted against azimuthal and radial mode order at the inlet and exhaust planes. Equipartition of incident modal power is assumed at the inlet. The selective effect of the acoustical treatment in attenuating specific modes is evident in the solution. Although intended for

Figure 5 FE computation of transmission in a turbofan bypass duct.²⁸ (a) Duct geometry, (b) FE mesh and modal variables, (c) incident modal powers, and (d) transmitted modal powers.

multimode solutions, the modal approach can also be applied to exhaust and induction systems where only one mode is cut-on.²⁹

7.2 Eigenmodes in Uniform Ducts

The acoustic field in a prismatic duct of constant cross section can be expressed as a sum of discrete eigenmodes. These are solutions of the homogeneous acoustic wave equation [see Eq. (1)], which take the form

$$P(\mathbf{x}, t) = \psi(x, y)e^{i\omega t - ik\lambda z} \quad (19)$$

where z is the duct axis, $\psi(x, y)$ is a transverse eigenmode and λ is a nondimensional axial wavenumber. The attenuation per unit length along the duct is proportional to the imaginary part of $k\lambda$. Substitution of expression (19) into the homogeneous version of (1) gives a two-dimensional Helmholtz equation of the form

$$\rho_0 \nabla_2 \left(\frac{1}{\rho_0} \nabla_2 p \right) + k^2 (1 - \lambda^2) p = 0 \quad (20)$$

where $\nabla_2 = (\partial/\partial x, \partial/\partial y)$. A finite element discretization in two dimensions analogous to that of Section 5 then gives an algebraic eigenvalue problem of the form

$$[\mathbf{K} + i\omega\mathbf{C} - \omega^2\mathbf{M}]\{\psi\} = -\lambda^2\omega^2[\mathbf{M}]\{\psi\} \quad (21)$$

where $[\mathbf{K}]$, $[\mathbf{C}]$, and $[\mathbf{M}]$ are two-dimensional equivalents of expressions (13) obtained by integrating over the duct cross section and around its perimeter. Eigenproblems of this type can be formed for local and bulk lined ducts and can include also structural coupling with the duct walls. The inclusion of mean flow in the airway of such ducts leads to a higher order problem in λ .³⁰ Results obtained from such a study are shown in Fig. 6. This shows an FE model for one cell of a “bar silencer” and includes a comparison of

measured and predicted axial attenuations. Such models have proven to be reliable predictors of the *least attenuated* mode that often dominates observed behavior. A similar approach has been applied in a modified form to predict attenuation in the capillary pores of automotive catalytic converters.³¹

8 UNBOUNDED PROBLEMS

New issues arise when FE methods are applied to unbounded problems. First, how to construct an artificial outer boundary to the FE domain, which will be transparent to outgoing disturbances, and second, how to reconstruct a far-field solution, which lies beyond the computational domain. Both issues are resolved by BE schemes that require no truncation surface and that embody an exact far-field representation. However, the BE approach is restricted in practice to problems for which an analytic free field Green’s function exists—in effect homogeneous problems. With this proviso, BE method schemes, particularly those based on *fast multipole* and associated methods^{3,32} currently offer the most efficient solution for homogeneous exterior problems. The case for traditional BE method is less conclusive.² Domain-based FE methods are important, however, in situations where the exterior field is inhomogeneous—due to temperature gradients or convective terms, for example—or at lower frequencies in situations where problem size is less important than ease of implementation and robustness, particularly in terms of coupling to structural models.

Many methods have been used to terminate the computational domain of exterior FE models. A comprehensive review of them lies beyond the scope of this chapter. Many are described in Refs. 33 and 34. They divide broadly into schemes that are local and non-local on the truncation boundary. *Nonlocal* methods include traditional mode matching, FE-DtN, and FE-BE models in which the FE domain is matched to a BE model at the truncation boundary. *Local* methods are generally preferable, especially for larger problems. FE

implementation of the first- or second-order boundary conditions of Bayliss, Gunzberger, and Turkel⁸ have been used extensively. Local conditions developed by Engquist and Majda and by Feng have also been used. Both are reviewed and summarized in Ref. 35. Absorbing and perfectly matched layers (PMLs) are also used, as are infinite element (IE) schemes. The latter have proved the most robust of all these methods for commercial exploitation and are implemented in major commercial codes such as SYSNOISE, ACTRAN, ABAQUS, and COMET. They have the advantage of being simple to integrate within conventional FE programs while offering a variable, high-order nonreflecting boundary condition. The order of the boundary treatment can be increased indefinitely subject only to conditioning issues at high orders.³⁶ The use of relatively high-order elements (typically in the range 10 to 15) means that an anechoic termination can be applied very close to the radiating or scattering body. The far-field directivity is given directly by such formulations and does not necessitate a Kirchhoff or Ffowcs-Williams Hawkins integration. The effectiveness of high-order infinite elements in resolving complex exterior fields is illustrated in Fig. 7. This shows a comparison of the exact and computed sound pressure amplitude for a plane wave scattered by a rigid sphere of diameter D for $kD = 20$. The exterior region is modeled entirely by infinite elements. These are shown on the left of the figure, truncated at $r = D$. Such models can also be used in the time domain³⁷ and extended to spheroidal and elliptical coordinate systems.³⁸

9 ACOUSTIC PROPAGATION ON MEAN FLOWS

9.1 Irrotational Mean Flow

When mean flow is present, the propagation of an acoustical disturbance is modified by convection. When the mean flow is irrotational, the convective effect can be modeled by formulating the acoustical problem in terms of the acoustic velocity potential and by solving a convected form of the wave equation or Helmholtz equation. FE and IE models based on

this approach have been used quite extensively to predict acoustic propagation in aeroengine intakes.^{28,39} A solution of this type is illustrated in Fig. 8. This shows the FE mesh and solution contours for a high-order spinning mode that is generated on the fan plane of a high bypass ratio turbofan engine and propagates to the free field. Increased resolution is required in the FE mesh in the near-sonic region close to the lip of the nacelle to capture the wave shortening effect of the adverse mean flow. The solution shown was obtained using the ACTRAN-AE code with quadratic finite elements and infinite elements of order 15. High-order spectral elements have been applied to similar three-dimensional problems with flow.²¹

9.2 Rotational Mean Flow

When the mean flow is rotational, the acoustical disturbance is coupled to vortical and entropy waves. The linearized Euler equations (LEE) must then be used. Structured, high-order, dispersion relation preserving (DRP) finite difference schemes⁵ are the method of choice for such problems, but FE time-domain schemes based on the discontinuous Galerkin method (DGM) have also proved effective. These combine low numerical dispersion with an unstructured grid.⁴⁰ Time-domain DGM is also well suited to parallel implementation. As with other time-domain LEE methods, DGM has the disadvantage, however, of introducing shear flow instabilities that must be damped or filtered to preserve the acoustical solution.⁴¹ Frequency-domain FE models based on the LEE formulation avoid these problems but are known to be unstable when a conventional Bubnov–Galerkin formulation is used with continuous test functions. A streamwise upwind Petrov Galerkin (SUPG) FE model has been proposed to remedy this deficiency.⁴² Alternatively, the Galbrun equations, which pose the flow acoustical problem in terms of Lagrangian displacements, can be used as the basis for a stable frequency-domain mixed FE model for propagation on shear flows.⁴³ Many uncertainties remain, however, regarding the treatment of shear instabilities and time-domain impedance boundary conditions in rotational flows.

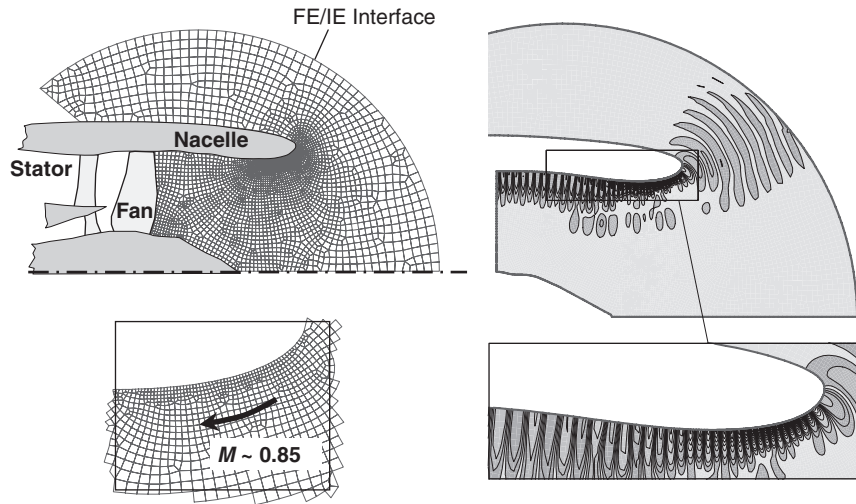

Figure 8 FE/IE solution for radiation from an engine intake with mean flow. FE mesh (left). Contours of instantaneous sound pressure (right). A spinning mode of azimuthal order 26 and radial order 1 is incident at the fan. $kR = 34$, $M_{\max} = 0.85$.

10 SOLVING LARGE PROBLEMS

Practical difficulties arise in solving the FE equations at high frequencies, particularly for three-dimensional problems where very large numbers of nodes are needed for *short-wavelength* solutions. This situation arises when the computational domain is much larger than the characteristic acoustic wavelength. Such problems are not uncommon in application areas such as medical ultrasound, aeroacoustics, underwater structural acoustics, and outdoor propagation. For two-dimensional or axisymmetric problems, the situation is tenable. If the *10 nodes per wavelength* rule is applied in two dimensions to a solution domain that extends for 10 acoustic wavelengths in each direction, the required mesh contains approximately 10,000 nodes. Such problems can be solved relatively easily using a direct solver and require only seconds or minutes of CPU time on a single 32-bit processor. An equivalent three-dimensional model of the same dimensions and with a similar acoustic wavelength and mesh resolution contains approximately 1,000,000 nodes. This poses an altogether different computational challenge. The direct solution of such a problem scales poorly with problem size,* and requires very many CPU hours and unacceptable memory requirements. Different approaches must, therefore, be adopted for such problems. Several strategies exist.

10.1 Indirect Solvers

The use of indirect solvers allows fully condensed storage to be used for the assembled coefficient matrices

*Technically, the scaling is as the third power of the matrix dimension for conventional direct solvers, but better performance is observed when advanced sparse solvers are used.

and greatly reduces overall storage requirements. Iterative solvers can also exploit fast vector operations and lend themselves to efficient parallel computation. However, the rate of convergence of standard iterative solvers[†] is poor for discrete Helmholtz problems and deteriorates with frequency. Diagonal and incomplete LU preconditioning leads to some improvement for problems of modest size,⁴⁴ but effective and robust general preconditioners for the Helmholtz problem have yet to be developed. An interesting variant here is the fictitious domain method⁴⁵ in which a regular rectangular mesh is used over most of the domain, adjusted only at domain boundaries to accommodate irregular shapes. The regularity of the mesh permits the construction of a highly effective preconditioner and permits the solution of very large homogeneous Helmholtz problems using an indirect parallel solver.

10.2 Domain Decomposition

Irrespective of whether iterative or direct methods are used, the key to developing a practical FE acoustical code for large problems lies currently in efficient parallelization on a distributed memory system such as a PC cluster. By distributing the solution over N processors the required CPU time can in theory be reduced by a factor $1/N$. This sharing of the solution across a number of processors is commonly achieved by domain decomposition whereby the physical solution domain is subdivided into overlapping or nonoverlapping subregions within which the solution is localized and dealt with by a single processor. Communication between processors is necessary and the extent to which this can be reduced tends to dominate the

[†]GMRES, QMR, and BiCGstab, for example.⁴⁸

relative efficiency of different domain decomposition approaches. General tools such as METIS* and PETSc† are available to assist the user in putting together combinations of solver and domain segmentation that balance the load on each processor and optimize parallel speedup. The reader is referred elsewhere for a full treatment of domain decomposition.⁴⁶ In the frequency domain, the finite element tearing and integration method (FETI) has been applied quite extensively to large Helmholtz problems, particularly in underwater scattering,⁴⁷ while more straightforward Schur-type methods have been applied to problems in aeroacoustic propagation.²¹ In both cases, problem sizes of the order 10^6 to 10^7 degrees of freedom are solved, albeit with some effort. In the case of Ref. 21, for example, 2.5 days of process time was required on 192 processors to solve a Helmholtz problem with 6.7×10^6 degrees of freedom. An equivalent time-domain DGM parallel formulation with 22×10^6 discretization points required comparable effort (10 days on 32 processors). While specialized acoustical FE codes such as SYS-NOISE and ACTRAN offer limited parallel capability at the time of writing, a truly efficient and robust, parallel acoustical FE code has yet to appear in the commercial domain.

A sort of domain decomposition which is widely used for large structural models but equally applicable to FE acoustics is automated multilevel substructuring (AMLS).⁴⁹ Here the problem size is reduced by projecting the FE solution vector onto a smaller set of eigenmodes. These are calculated not for the model as a whole but for substructures obtained by using an automated domain decomposition procedure (such as METIS). This reduces a large and intractable eigenvalue problem to a series of smaller problems of reduced dimensions. While AMLS is routinely used for structural problems—within the automated component mode synthesis (ACMS) facility of MSC/NASTRAN, for example—its potential for purely acoustical problems has not yet been realized.

10.3 Alternative Spatial Representations

As an alternative—or adjunct—to the use of more efficient solvers to reduce solution times for large problems, the number of equations itself can be reduced prior to solution by more effective discretization. The constraint here in conventional FE codes is the *nodes per wavelength* requirement, exacerbated by pollution error at high frequencies. A possible remedy for this *impasse* is the use of nonpolynomial bases that are able to capture more accurately the wavelike character of the solution. More specifically, an argument can be made that the inclusion of approximate or exact *local* solutions of the governing equations within the

trial solution will improve spatial resolution. This concept underpins several contemporary approaches to FE computation of wave problems. In the case of the Helmholtz equation, local plane wave solutions are used for this purpose. It then becomes possible, in theory, to accurately represent many wavelengths of the solution within a single element, eliminating the nodes per wavelength requirement altogether.

The partition of unity (PUM) approach proposed initially by Babuska and Melenk and developed by Bettess and Laghrouche⁵⁰ provides a simple illustration of this philosophy. In an FE implementation of the PUM for the Helmholtz problem, the trial solution of Eq. (10) is replaced by one in which each nodal shape function is “enriched” by a set of discrete plane waves. This gives a trial solution of the form

$$\tilde{p}(\mathbf{x}, \omega) = \sum_{j=1}^n \sum_{l=1}^m q_{jl}(\omega) \psi_{jl}(\mathbf{x}) \quad \text{where} \\ \psi_{jl}(\mathbf{x}) = N_j(\mathbf{x}) e^{-i\mathbf{k}_{lj}(\mathbf{x}-\mathbf{x}_j)} \quad (22)$$

The numerical solution is, therefore, defined by $m \times n$ unknown parameters (q_{jl} , $j = 1, \dots, n$, $l = 1, \dots, m$,) where each node has m degrees of freedom. Each of these represents the amplitude of a plane wave propagating with a discrete wavenumber \mathbf{k}_{lj} . In the case of an inhomogeneous or anisotropic medium the magnitude and direction of the wavenumber \mathbf{k}_{lj} can be chosen so that it represents an exact or approximate local solution at node j . In this sense the basis functions, $\psi_{jl}(\mathbf{x})$, have been enriched by the inclusion of information about the local solution. The construction of $\psi_{jl}(\mathbf{x})$ as the product of a conventional nodal shape function and a local wave approximation is illustrated in Fig. 9.

In all other respects the PUM variational formulation is the same as that of a conventional FE model, although element integrations become more time consuming since the basis functions are highly oscillatory within each element. If the true solution corresponds to a plane wave propagating in one of the discrete wave directions, the numerical solution will represent it without approximation. In real cases, where a spectrum of wave components are present, the PUM solution will attempt to fit these to an ensemble of discrete waves modulated by the conventional element shape functions.

The accuracy of PUM and conventional FE models are compared in Fig. 9b. Mesh resolution is characterized by the number of degrees of freedom per wavelength.[‡] Figure 9 shows the L_2 error for the computed acoustic field in a 2D lined duct. A prescribed set of positive and negative running modes are injected at one end of the duct and a compatible impedance

*See METIS homepage, <http://www-users.cs.umn.edu/karypis/metis>.

†Portable Extensible Toolkit for Scientific computation, see <http://www.mcs.anl.gov/petsc>.

‡This is obtained for an unstructured 2D mesh by multiplying the square root of the number of degrees of freedom per unit area by the characteristic acoustic wavelength $\lambda = 2\pi/k$.

Figure 9 (a) The PUM basis function. (b) PUM and quadratic FEM (QFEM) solution error as a function of mesh resolution. 2D uniform lined duct, $kL = 40$, $M = 0.25$. Condition number indicated in parentheses (10^n) for selected data points.

condition is applied at the other. The comparison is made for a mean flow of Mach number 0.25. The percentage L_2 error is plotted against mesh resolution for a number of PUM meshes with different numbers of wave directions at each node, and for coarse, medium, and fine conventional FE meshes based on quadratic polynomial elements (QFEM). The PUM meshes are characterized by the number of wave directions, m . It is clear that the accuracy of the PUM solution can be improved either by refining the mesh (dashed line) or by increasing the number of wave directions (solid line), the latter being the more effective. In the case of the conventional scheme, the first option only is available. In all cases, however, the PUM is clearly more accurate for a given number of degrees of freedom than the conventional QFEM. The only obstacle to improving accuracy indefinitely is one of conditioning. The condition number of the coefficient matrix for the PUM model becomes large as the number of waves increases or as the frequency decreases. This is undesirable and mitigates against any use of iterative solution methods. The order of magnitude of the condition number for selected data points is indicated in parentheses in Fig. 9b.

The PUM approach is by no means alone in using a plane wave basis to improve resolution. The same philosophy underpins a number of recent FE formulations. These include the discontinuous enrichment method⁵¹ and the ultraweak variational formulation.⁵² A similar concept is implicit in recent meshless methods proposed for the Helmholtz problem.⁵³

11 CONCLUDING COMMENTS

The application of finite elements in acoustics is now a relatively mature technology. Robust commercial

codes are available that deal well with standard linear analyses and permit accurate predictions to be made for acoustical and acoustical-structural problems that include the effects of absorption and radiation. Acoustic propagation on mean flows is also becoming available to general users and this trend will continue as the demand for accurate aeroacoustic modeling grows for turbomachinery, automotive, and other applications. FE acoustical analysis is restricted at the current time mainly to low and moderate frequency cases. This is a practical rather than a theoretical limitation and will diminish in the years to come as more effective parallel acoustical codes are developed and as new more efficient element formulations are improved and refined. The principal advantages of the finite element approach remain its ability to model arbitrarily shaped acoustical domains using unstructured meshes and its inherent capacity for dealing with material and other inhomogeneities in a seamless fashion.

CHAPTER 8

BOUNDARY ELEMENT MODELING

D. W. Herrin, T. W. Wu, and A. F. Seybert

Department of Mechanical Engineering
University of Kentucky
Lexington, Kentucky

1 INTRODUCTION

Both the boundary element method (BEM) and the finite element method (FEM) approximate the solution in a piecewise fashion. The chief difference between the two methods is that the BEM solves the acoustical quantities on the boundary of the acoustical domain (or air) instead of in the acoustical domain itself. The solution within the acoustical domain is then determined based on the boundary solution. This is accomplished by expressing the acoustical variables within the acoustical domain as a surface integral over the domain boundary. The BEM has been used to successfully predict (1) the transmission loss of complicated exhaust components, (2) the sound radiation from engines and compressors, and (3) passenger compartment noise.

In this chapter, a basic theoretical development of the BEM is presented, and then each step of the process for conducting an analysis is summarized. Three practical examples illustrate the reliability and application of the method to a wide range of real-world problems.

2 BEM THEORY

An important class of problems in acoustics is the propagation of sound waves at a constant frequency ω . For this case, the sound pressure \hat{P} at any point fluctuates sinusoidally with frequency ω so that $\hat{P} = pe^{i\omega t}$ where p is the complex amplitude of the sound pressure fluctuation. The complex exponential allows us to take into account sound pressure magnitude and phase from point-to-point in the medium.

The governing differential equation for linear acoustics in the frequency domain for p is the Helmholtz equation:

$$\nabla^2 p + k^2 p = 0 \quad (1)$$

where k is the wavenumber ($k = \omega/c$). The boundary conditions for the Helmholtz equation are summarized in Table 1.

For exterior problems, the boundary integral equation¹

$$C(P)p(P) = \int_S \left(\frac{\partial p}{\partial n} G(r) - p \frac{\partial G(r)}{\partial n} \right) dS \quad (2)$$

can be developed using the Helmholtz equation [Eq. (1)], Green's second identity, and the Sommerfeld

Table 1 Boundary Conditions for Helmholtz Equation

Boundary Condition	Physical Quantity	Mathematical Relation
Dirichlet	Sound pressure (p_e)	$p = p_e$
Neumann	Normal velocity (v_n)	$\frac{\partial p}{\partial n} = -i\omega\rho v_n$
Robin	Acoustic impedance (Z_a)	$\frac{\partial p}{\partial n} = -i\omega\rho \frac{1}{Z_a} p$

Figure 1 Schematic showing the variables for the direct boundary element method.

radiation condition.¹⁻³ The variables are identified in Fig. 1. If complex exponential notation is adopted, the kernel in Eq. (2) or the Green's function is

$$G(r) = \frac{e^{-ikr}}{4\pi r} \quad (3)$$

where r is the distance between the collocation point P and the integration point Q on the surface. Equation (3) is the expression for a point monopole source in three dimensions. The lead coefficient $C(P)$ in Eq. (2) is a constant that depends on the location of the collocation point P . For interior problems, the direct BEM formulation is identical to that shown in Eq. (2) except that the lead coefficient $C(P)$ is replaced by $C^0(P)$, which is defined differently.^{1,2} Table 2 shows how both lead coefficients are defined

Table 2 Lead Coefficient Definitions at Different Locations

Location of P	$C(P)$	$C^0(P)$
In acoustical domain V	1	1
Outside acoustical domain V	0	0
Smooth boundary	$\frac{1}{2}$	$\frac{1}{2}$
Corners/edges	$1 - \int_S \frac{\partial}{\partial n} \left(\frac{1}{4\pi r} \right) dS$	$-\int_S \frac{\partial}{\partial n} \left(\frac{1}{4\pi r} \right) dS$

depending on whether the problem is an interior or exterior one.

For direct or collocation approaches,¹⁻¹⁹ the boundary must be closed, and the primary variables are the sound pressure and normal velocity on the side of the boundary that is in contact with the fluid. The normal velocity (v_n) can be related to the $\partial p / \partial n$ term in Eq. (2) via the momentum equation that is expressed as

$$\frac{\partial p}{\partial n} = -i\rho\omega v_n \quad (4)$$

where ρ is the mean density of the fluid.

When using the direct BEM, there is a distinction between an interior and exterior problem. However, there is no such distinction using indirect BEM approaches.²⁰⁻²⁸ Both sides of the boundary are considered simultaneously even though only one side of the boundary may be in contact with the fluid. As Fig. 2 indicates, the boundary consists of the inside (S_1) and outside surfaces (S_2), and both sides are analyzed at the same time.

In short, boundary integral equations like Eq. (2) can be written on both sides of the boundary and then summed resulting in an indirect boundary integral formulation that can be expressed as

$$p(P) = \int_S \left[G(r) \delta p - \frac{\partial G(r)}{\partial n} \delta p \right] dS \quad (5)$$

**Figure 2** Schematic showing the variables for the indirect boundary element method.

In Eq. (5), the primary variables are the single- (δp) and double-layer (δp) potentials. The single-layer potential (δp) is the difference in the normal gradient of the pressure and can be related to the normal velocities (v_{n1} and v_{n2}), and the double-layer potential (δp) is the difference in acoustic pressure (p_1 and p_2) across the boundary of the BEM model. Since S_1 is identical to S_2 , the symbol S is used for both in Eq. (5) and the normal vector is defined as pointing away from the acoustical domain.

Table 3 summarizes how the single- and double-layer potentials are related to the normal velocity and sound pressure. If a Galerkin discretization is adopted, the boundary element matrices will be symmetric, and the solution of the matrices will be faster than the direct method provided a direct solver is used.²¹ Additionally, the symmetric matrices are preferable for structural-acoustical coupling.²⁵ The boundary conditions for the indirect BEM are developed by relating the acoustic pressure, normal velocity, and normal impedance to the single- and double-layer potentials.

More thorough descriptions for the direct and indirect BEM are presented by Wu³ and Vlahopoulos,²⁷ respectively. It should be mentioned that the differences between the so-called direct and indirect approaches have blurred recently. In fact, high-level studies by Wu²⁹ and Chen et al.^{30,31} combine both procedures into one set of equations. Chen et al. developed a direct scheme using Galerkin discretization, which generated symmetric matrices. However, these state-of-the-art approaches are not used in commercial software at the time of this writing.

3 MESH PREPARATION

Building the mesh is the first step in using the BEM to solve a problem. Figure 3 shows a BEM model used for predicting the sound radiation from a gear housing. The geometry of the housing is represented by a BEM mesh, a series of points called nodes on the surface of the body that are connected to form elements of either quadrilateral or triangular shape.

Most commercially available pre- and postprocessing programs developed for the FEM may also be used for constructing BEM meshes. In many instances, a solid model can be built, and the surface of the solid can be meshed automatically creating a mesh representative of the boundary. Alternatively, a wire frame or surface model of the boundary could be created using computer-aided design (CAD) software and then meshed. Regardless of the way the mesh is prepared, shell elements are typically used in the finite element

Table 3 Relationship of Single- and Double-Layer Potentials to Boundary Conditions

Potential	Symbol	Mathematical Relation
Single layer	δp	$\frac{\delta p_1}{\delta n} - \frac{\delta p_2}{\delta n}$
Double layer	δp	$p_1 - p_2$

Figure 3 Boundary element model of a gear housing.

preprocessor, and the nodes and elements are transferred to the boundary element software. The material properties and thickness of the elements are irrelevant since the boundary elements only bound the domain.

Sometimes a structural finite element mesh is used as a starting point for creating the boundary element mesh. Sometimes a boundary element mesh can be obtained by simply “skinning” the structural finite element mesh. However, the structural finite element mesh is often excessively fine for the subsequent acoustical boundary element analyses, leading to excessive CPU (central processing unit) time. Commercially available software packages have been developed to skin and then coarsen structural finite element meshes.^{32,33} These packages can automatically remove one-dimensional elements like bars and beams, and skin three-dimensional elements like tetrahedrons with two-dimensional boundary elements. Then, the skinned model can be coarsened providing the user with the desired BEM mesh. An example of a skinned and coarsened model is shown in Figure 4.

Figure 4 Schematic showing a boundary element model that was created using the finite element model as a starting point.

It is well known that the BEM can be CPU intensive if the model has a large number of nodes (i.e., degrees of freedom). The solution time is roughly proportional to the number of nodes cubed for a BEM analysis, although iterative solvers may reduce the solution time. Nevertheless, if solution time is an issue and it normally is, it will be advantageous to minimize the number of nodes in a BEM model.

Unfortunately, the accuracy of the analysis depends on having a sufficient number of nodes in the model. Thus, most engineers try to straddle the line between having a mesh that will yield accurate results yet can be solved quickly. The general rule of thumb is that six linear or three parabolic elements are needed per acoustic wavelength. However, these guidelines depend on the geometry, boundary conditions, desired accuracy, integration quadrature, and solver algorithm.^{34,35} Therefore, these guidelines should not be treated as strict rules.

One notable exception to the guidelines is the case where the normal velocity or sound pressure on the boundary is complicated. Accordingly, the boundary mesh and the interpolation scheme will need to be sufficient to represent the complexity of this boundary condition. This may require a much finer mesh than the guidelines would normally dictate. Regardless of the element size, the shape of the element appears to have little impact on the accuracy of the analysis, and triangular boundary elements are nearly as accurate as their quadrilateral counterparts.³⁴

One way to minimize the number of nodes without losing any precision is to utilize symmetry when appropriate. The common free space Green's function [Eq. (3)] was used for the derivation earlier in the chapter. However, the Green's function can take different forms if it is convenient to do so. For example, the half-space Green's function could be used for modeling a hemisphere radiation problem.

Similarly, different Green's functions can be used for the axisymmetric and two-dimensional cases.² Symmetry planes may also be used to model rigid floors or walls provided that the surface is infinite or can be approximated as such.

The direction of the element normal to the surface is another important aspect of mesh preparation. The element normal direction is determined by the sequence of the nodes defining a particular element. If the sequence is defined in a counterclockwise fashion, the normal direction will point outward. Figure 5 illustrates this for a quadrilateral element. The element normal direction should be consistent throughout the boundary element mesh. If the direct BEM is used, the normal direction should point to or away from the acoustical domain depending on the convention used by the BEM software. In most instances, adjusting the normal direction is trivial since most commercial BEM software has the built-in smarts to reverse the normal direction of a mesh or to make the normal direction consistent.

4 FLUID PROPERTY SPECIFICATION

After the mesh is defined, the fluid properties for the acoustical domain can be specified. The BEM assumes that the fluid is a homogeneous ideal fluid in the linear regime. The fluid properties consist of the speed of sound and the mean density.

In a BEM model, a sound-absorbing material can be modeled as either locally reacting or bulk reacting. In the local reacting case, the surface impedance is used as a boundary condition (see Table 1). In the bulk-reacting case, a multidomain^{36,37} or direct-mixed body BEM³⁸ analysis should be performed, using bulk-reacting properties to model the absorption. Any homogeneous sound-absorbing material can be described in terms of its bulk properties. These bulk properties include both the complex density and speed of sound for a medium³⁹ and provide an ideal mechanism for modeling the losses of a sound-absorbing material. Bulk-reacting properties are especially important for thick sections of sound-absorbing materials.

As mentioned previously, the BEM assumes that the domain is homogeneous. However, a nonhomogeneous domain could be divided into several smaller

Figure 5 Manner in which the normal direction is defined for a boundary element.

Figure 6 Passenger compartment modeled as two separate acoustical domains.

Figure 7 Comparison of the transmission loss for a lined expansion chamber using local and bulk reacting models.

subdomains having different fluid properties. Where the boundaries are joined, continuity of particle velocity and pressure is enforced. For example, the passenger compartment shown in Figure 6 could be modeled as two separate acoustical domains, one for the air and another for the seat. The seat material properties would be the complex density and speed of sound of the seat material. Another application is muffler analysis with a temperature variation. Since the temperature variations in a muffler are substantial, the speed of sound and density of the air will vary from chamber to chamber. Using a multidomain BEM, each chamber can be modeled as a separate subdomain having different fluid properties.

The advantage of using a bulk-reacting model is illustrated in Figure 7. BEM transmission loss predictions are compared to experimental results for a packed expansion chamber with 1-inch-thick sound-absorbing material.³⁸ Both locally and bulk-reacting models were used to simulate the sound absorption. The results using a bulk-reacting model are superior, corresponding closely to the measured transmission loss.

5 BOUNDARY CONDITIONS

The boundary conditions for the BEM correspond to the Dirichlet, Neumann, and Robin conditions for

Figure 8 Schematic showing the boundary conditions for the direct BEM.

Helmholtz equation (as shown in Table 1). Figure 8 shows a boundary element domain for the direct BEM. The boundary element mesh covers the entire surface of the acoustical domain. At each node on the boundary, a Dirichlet, Neumann, or Robin boundary condition should be specified. In other words, a sound pressure, normal velocity, or surface impedance should be identified for each node. Obtaining and/or selecting these boundary conditions may be problematic. In many instances, the boundary conditions may be assumed or measured. For example, the normal velocity can be obtained by a FEM structural analysis, and the surface impedance can be measured using a two-microphone test.⁴⁰ Both the magnitude and the phase of the boundary condition are important. Most commercial BEM packages select a default zero normal velocity boundary condition (which corresponds to a rigid boundary) if the user specifies no other condition.

The normal velocity on the boundary is often obtained from a preliminary structural finite element analysis. The frequency response can be read into BEM software as a normal velocity boundary condition. It is likely that the nodes in the FEM and BEM models are not coincident with one another. However, most commercial BEM packages can interpolate the results from the finite element mesh onto the boundary element mesh.

For the indirect BEM, the boundary conditions are the differences in the pressure, normal velocity, and surface impedance across the boundary. Figure 9 illustrates the setup for an indirect BEM problem. Boundary conditions are applied to both sides of the elements. Each element has a positive and negative side that is identified by the element normal direction (see Fig. 9). Most difficulties using the indirect BEM are a result of not recognizing the ramifications of specifying boundary conditions on both sides of the element.

To model an opening using the indirect BEM, a zero jump in pressure^{27,28} should be applied to the edges of the opening in the BEM mesh (Fig. 10). Most commercial BEM software has the ability to locate nodes around an opening so that the user can easily apply the zero jump in pressure. Additionally,

Figure 9 Schematic showing the boundary conditions for the indirect BEM.

Figure 10 Special boundary conditions that may be used with the indirect BEM.

special treatment is important when modeling three or more surfaces that intersect (also illustrated in Fig. 10). Nodes must be duplicated along the edge and compatibility conditions must be applied.^{27,28} Though this seems complicated, commercial BEM software can easily detect and create these junctions applying the appropriate compatibility conditions.

Many mufflers utilize perforated panels as attenuation mechanisms, and these panels may be modeled by specifying the transfer impedance of the perforate.^{41,42} The assumption is that the particle velocity is continuous on both sides of the perforated plate but the sound pressure is not. For example, a perforated plate is shown in Fig. 11. A transfer impedance boundary condition can be defined at the perforated panel and expressed as

$$Z_{tr} = \frac{p_1 - p_2}{v_n} \quad (6)$$

Figure 11 Schematic showing the variables used to define the transfer impedance of a perforate.

Figure 12 Transmission loss for a concentric tube resonator with a perforate.

where Z_{tr} is the transfer impedance, p_1 and p_2 are the sound pressures on each side of the plate, and v_n is the particle velocity. The transfer impedance can be measured or estimated using empirical formulas. In these empirical formulas, the transfer impedance is related to factors like the porosity, thickness, and hole diameter of a perforated plate.^{43,44} Figure 12 shows the transmission loss results computed using the BEM results for an expansion chamber with a perforated tube.

Another useful capability is the ability to specify acoustic point sources in a BEM model. Noise sources can be modeled as a point source if they are acoustically small (i.e., the dimensions of a source are small compared to an acoustic wavelength) and omnidirectional. Both the magnitude and the phase of the point source should be specified.

6 SPECIAL HANDLING OF ACOUSTIC RADIATION PROBLEMS

The BEM is sometimes preferred to the FEM for acoustic radiation problems because of the ease in meshing. However, there are some solution difficulties with the BEM for acoustic radiation problems. Both the direct and indirect methods have difficulties that are similar but not identical. With the direct BEM, the exterior boundary integral equation does not have a unique solution at certain frequencies. These frequencies correspond to the resonance frequencies of the airspace interior to the boundary (with Dirichlet boundary conditions). Though the direct BEM results will be accurate at most frequencies, the sound pressure results will be incorrect at these characteristic frequencies.

The most common approach to overcome the nonuniqueness difficulty is to use the combined Helmholtz integral equation formulation, or CHIEF, method.¹¹ A few overdetermination or CHIEF points are placed inside the boundary, and CHIEF equations are written that force the sound pressure to be equal to zero at each of these points. Several CHIEF points should be identified inside the boundary because a CHIEF point that falls on or near the interior nodal surface of a particular eigenfrequency will not provide

a strong constraint since the pressure on that interior nodal surface is also zero for the interior problem. As the frequency increases, the problem is compounded by the fact that the eigenfrequencies and the nodal surfaces become more closely spaced. Therefore, analysts normally add CHIEF points liberally if higher frequencies are considered. Although the CHIEF method is very effective at low and intermediate frequencies, a more theoretically robust way to overcome the nonuniqueness difficulty is the Burton and Miller method.⁵

Similarly, for an indirect BEM analysis, there is a nonexistence difficulty associated with exterior radiation problems. Since there is no distinction between the interior and exterior analysis, the primary variables of the indirect BEM solution capture information on both sides of the boundary.²⁷ At the resonance frequencies for the interior, the solution for points on the exterior is contaminated by large differences in pressure between the exterior and interior surfaces of the boundary. The nonexistence difficulty can be solved by adding absorptive planes inside or by specifying an impedance boundary condition on the interior surface of the boundary.²⁷

The lesson to be learned is that exterior radiation problems should be approached carefully. However, excellent acoustical predictions can be made using the BEM, provided appropriate precautions are taken.

7 BEM SOLUTION

Even though BEM matrices are based on a surface mesh, the BEM is often computationally and memory intensive. Both the indirect and direct procedures produce dense matrices that are not sparse, as is typical of finite element matrices. For realistic models, the size of the matrix could easily be on the order of tens of thousands. The memory storage of an $N \times N$ matrix is on the order of N^2 , while the solution time using a direct solver is on the order of N^3 . As the BEM model grows, the method sometimes becomes impractical due to computer limitations.

One way to overcome the solution time difficulty is to use an iterative solver⁴⁵ with some appropriate preconditioning.^{46,47} Iterative solvers are much faster than conventional direct solvers for large problems.⁴⁸ Also, there is no need to keep the matrix in memory, although the solution is slower in that case.⁴⁹ Additionally, BEM researchers have been working on different variations of the so-called fast multipole expansion method based on the original idea by Rokhlin⁵⁰⁻⁵³ in applied physics.

8 POSTPROCESSING

Boundary element results can be viewed and assessed in a number of different ways. The BEM matrix solution only computes the acoustical quantities on the surface of the boundary element mesh. Thus, only the sound pressure and/or normal velocity is computed on the boundary using the direct method, and only the single- and/or double-layer potentials are computed using the indirect BEM. Following this, the acoustical

quantities at points in the field can be determined from the boundary solution by integrating the surface acoustical quantities over the boundary, a process requiring minimal computer resources. As a result, once an acoustical BEM analysis has been completed, results can be examined at any number of field points in a matter of minutes. This is a clear advantage of using numerical approaches like the BEM over the time-intensive nature of experimental work. However, the numerical results in the field are only as reliable as the calculated acoustical quantities on the boundary, and the results should be carefully examined to assure they make good engineering sense.

To help evaluate the results, commercial software includes convenient postprocessing capabilities to determine and then plot the sound pressure results on standard geometric shapes like planes, spheres, or hemispheres in the sound field. These shapes do not have to be defined beforehand, making it very convenient to examine results at various locations of interest in the sound field. Furthermore, the user can more closely inspect the solution at strategic positions. For example, Fig. 13 shows a sound pressure contour for the sound radiated by an engine cover. A contour plot of the surface vibration is shown under the engine cover proper, and the sound pressure results are displayed on a field point mesh above the cover and give a good indication of the directivity of the sound at that particular frequency.

Additionally, the sound power can be computed after the matrix solution is completed. One advantage of the direct BEM is that the sound power and radiation efficiency can be determined from the boundary solution directly. This is a direct result of only one side of the boundary being considered for the solution. However, determining the sound power using the indirect BEM is a little more problematic. Normally, the user defines a sphere or some other geometric shape that encloses the sound radiator. After the sound pressure and particle velocity are computed on the

geometric shape, the sound power can be determined by integrating the sound intensity over the area of the shape. Results are normally better if the field points are located in the far field.

Another possible use of BEM technology can be to identify the panels that contribute most to the sound at a point or to the sound field as a whole. For instance, a BEM mesh was painted onto a diesel engine and then vibration measurements were made at each node on the engine surface. The measured vibrations were used as the input velocity boundary condition for a subsequent BEM calculation. The sound power contributions (in decibels) from the oil pan and the front cover of a diesel engine are shown in Fig. 14. As the figure indicates, the front cover is the prime culprit at 240 Hz. This example illustrates how the BEM can be used as a diagnostic tool even after a prototype is developed.

Boundary element method postprocessing is not always a turnkey operation. The user should carefully examine the results first to judge whether confidence is warranted in the analysis. Furthermore, unlike measurement results, raw BEM results are always on a narrow-band basis. Obtaining the overall or A-weighted sound pressure or sound power may require additional postprocessing depending on the commercial software used. Also, the transmission loss for a muffler or a plenum system cannot be exported directly using many BEM software packages. This requires additional postprocessing using a spreadsheet or mathematical software.

9 EXAMPLE 1: CONSTRUCTION CAB

A construction cab is an example of an interior acoustics problem. The construction cab under consideration is $1.9 \times 1.5 \times 0.9 \text{ m}^3$. Due to the thickness of the walls, and the high damping, the boundary was assumed to be rigid. A loudspeaker and tube were attached to the construction cab, and the sound pressure was measured using a microphone where the tube connects to the cab. All analyses were conducted at low enough frequencies so that plane waves could be assumed inside the tube. Medium-density foam was placed on the floor of the cab.

First, a solid model of the acoustical domain was prepared, and the boundary was meshed using shell elements. A commercial preprocessor was used to prepare the mesh, which was then transferred into BEM software. In accordance with the normal convention for the commercial BEM software in use, the element normal direction was checked for consistency and chosen to point toward the acoustical domain. For the indirect BEM, the normal direction must be consistent, pointing toward the inside or outside.

In this case, both the direct and indirect BEM approaches were used. For the indirect BEM, the boundary conditions are placed on the inner surface, and the outer surface is assumed to be rigid (normal velocity of zero). For both approaches, the measured sound pressure at the tube inlet was used as a boundary condition, and a surface impedance was applied to the floor to model the foam. (The surface impedance of the foam was measured in an impedance tube.⁴⁰) All

Figure 13 Contour plot showing the sound pressure variation on a field point plane located above an engine cover.

Figure 15 Schematic showing the BEM mesh and boundary conditions for the passenger compartment of a construction cab.

other surfaces aside from the floor were assumed to be rigid. The boundary conditions are shown in Fig. 15.

Since the passenger compartment airspace is modally dense, a fine frequency resolution of 5 Hz was used. The sound pressure results are compared at a point in the interior to measured results in Fig. 16. The results demonstrate the limits of the BEM. Although the boundary element results do not exactly match the measured results, the trends are predicted well and the overall sound pressure level is quite close. Determining

the pressure at a single point is arguably the most challenging test for a boundary element analysis. The BEM fares better when the sound power is predicted since the sound pressure results are used in an overall sense.

10 EXAMPLE 2: ENGINE COVER IN A PARTIAL ENCLOSURE

The sound radiation from an aluminum engine cover in a partial enclosure was predicted using the indirect BEM.⁵⁴ The experimental setup is shown in Fig. 17. The engine cover was bolted down at 15 locations to three steel plates bolted together ($\frac{3}{4}$ inches thick each). The steel plates were rigid and massive compared to the engine cover and were thus considered rigid for modeling purposes. A shaker was attached to the engine cover by positioning the stinger through a hole drilled through the steel plates, and high-density particleboard was placed around the periphery of the steel plates. The experiment was designed so that the engine cover could be assumed to lie on a rigid half space. The engine cover was excited using white-noise excitation inside a hemianechoic chamber.

To complicate the experiment, a partial enclosure was placed around the engine cover. The plywood partial enclosure was 0.4 m in height and was lined with glass fiber on each wall. Although the added enclosure is a simple experimental change, it had a significant impact on the sound radiation and the way in which the acoustical system is modeled. This problem is no longer strictly exterior or interior since the enclosure is open, making the model unsuitable for the direct BEM; the indirect BEM was used.

Figure 16 Sound pressure level comparison at a point inside the construction cab. (The overall A-weighted sound pressure levels predicted by BEM and measured were 99.7 dB and 97.7 dB respectively.)

Figure 17 Schematic showing the experimental setup of an engine cover located inside a partial enclosure.

the vibration results from the structural finite element model onto the surface of the boundary element mesh.

A symmetry plane was placed at the base of the engine cover to close the mesh. Since this is an acoustic radiation problem, precautions were taken to avoid errors in the solution due to the nonexistence difficulty for the indirect BEM discussed earlier. Two rectangular planes of boundary elements were positioned at right angles to one another in the space between the engine cover boundary and the symmetry plane (Fig. 18). An impedance boundary condition was applied to each side of the planes. Since the edges of each plane are free, a zero jump in pressure was applied along the edges.

A structural finite element model of the cover was created from a solid model of the engine cover. The solid model was automatically meshed using parabolic tetrahedral finite elements, and a frequency response analysis was performed. The results of the finite element analysis were used as a boundary condition for the acoustical analysis that followed.

Using the same solid model as a starting point, the boundary element mesh was created by meshing the outer surface of the solid with linear quadrilateral elements. The boundary element mesh is simpler and coarser than the structural finite element mesh. Since features like the small ribs have dimensions much less than an acoustic wavelength, they have a negligible effect on the acoustics even though they are significant structurally. Those features were removed from the solid model before meshing so that the mesh was coarser and could be analyzed in a timely manner. The boundary condition for the engine cover is the vibration on the cover (i.e., the particle velocity). The commercial BEM software used was able to interpolate

Figure 18 Schematic showing the boundary conditions that were assumed for a vibrating engine cover inside a partial enclosure.

Figure 19 Comparison of the sound power from the partial enclosure. Indirect BEM results are compared with those obtained by measurement. (The overall A-weighted sound power levels predicted by BEM and obtained by measurement were both 97.6 dB.)

The thickness of the partial enclosure was neglected since the enclosure is thin in the acoustical sense (i.e., the combined thickness of the wood and the absorptive lining is small compared to an acoustic wavelength). A surface impedance boundary condition was applied on the inside surface of the elements, and the outside surface was assumed to be rigid (zero velocity boundary condition). As indicated in Fig. 18, a zero jump in pressure was applied to the nodes on the top edge.

As Fig. 19 shows, the BEM results compared reasonably well with the experimental results. The closely matched A-weighted sound power results are largely a result of predicting the value of the highest peak accurately. The differences at the other peaks can be attributed to errors in measuring the damping of the engine cover. A small change in the damping will have a large effect on the structural FEM analysis and a corresponding effect on any acoustic computational analysis that follows. Measuring the structural damping accurately is tedious due to data collection and experimental setup issues involved.

11 CONCLUSION

The objective of this chapter was to introduce the BEM, noting some of the more important developments as well as the practical application of the method to a wide variety of acoustic problems. The BEM is a tool that can provide quick answers provided that a suitable model and realistic boundary conditions can be applied. However, when the BEM is looked at objectively, many practitioners find that it is not quite

what they had hoped for. Today, many problems are still intractable using numerical tools in a purely predictive fashion. For example, forces inside machinery (i.e., engines and compressors) are difficult to quantify. Without realistic input forces and damping in the structural FEM model, numerical results obtained by a subsequent BEM analysis should be considered critically. Certainly, the BEM may still be useful for determining the possible merits of one design over another. Nevertheless, it is hard to escape the suspicion that many models may not resemble reality as much as we would like.

CHAPTER 10

NONLINEAR ACOUSTICS

1 INTRODUCTION

In many practical cases, the propagation, reflection, transmission, refraction, diffraction, and attenuation of sound can be described using the linear wave equation. If the sound wave amplitude becomes large enough, or if sound waves are transmitted over considerable distances, then nonlinear effects occur. These effects cannot be explained with linear acoustics theory. Such nonlinear phenomena include waveform distortion and subsequent shock front formation, frequency spreading, nonlinear wave interaction (in contrast to simple wave superposition) when two or more waves intermingle, nonlinear attenuation, radiation pressure, and streaming. Additionally in liquids, cavitation and “water hammer” and even sonoluminescence can occur.

2 DISCUSSION

In most noise control problems, only a few nonlinear effects are normally of interest and these occur either first in intense noise situations, for example, close to jet or rocket engines or in the exhaust systems of internal combustion engines, or second in sound propagation over great distances in environmental noise problems. The first effect—the propagation of large amplitude sound waves—can be quite pronounced, even for propagation over short distances. The second, however, is often just as important as the first, and is really the effect that most characterizes nonlinear sound propagation. In this case nonlinear effects occur when small, but finite amplitude waves travel over sufficiently large distances. Small local nonlinear phenomena occur, which, by accumulating effects over sufficient distances, seriously distort the sound waveform and thus its frequency content. We shall mainly deal with these two situations in this brief chapter. For more detailed discussions the reader is referred to several useful and specialized books or book chapters on nonlinear acoustics.^{1–9}

The second effect described, waveform distortion occurring over large distances, has been known for a long time. Stokes described this effect in a paper¹⁰ in

Figure 1 Wave steepening predicted by Stokes.¹⁰

1848 and gave the first clear description of waveform distortion and steepening. See Fig. 1.

More recent theoretical and experimental results show that nonlinear effects cause any periodic disturbance propagating through a nondispersive medium to be transformed into a sawtooth one at large distances from its origin. In its travel through a medium, which is quadratically nonlinear, the plane wave takes the form of a “saw blade” with triangular “teeth.” The transformation of periodic wave signals into sawtooth signals is shown in Fig. 2a. As the distance, x ,

Figure 2 Examples of wave steepening from Rudenko.²²

*Present address: Department of Acoustics, Physics Faculty, Moscow State University, 119992 Moscow, Russia.

from the origin of the sound signal increases, any fine details in the initial wave profile become smoothed out through dissipation, during the wave propagation. The final wave profile is the same for both a simple harmonic signal (curve 1) and a more complicated complex harmonic signal (curve 2) at some distance from the source ($x = x_2$ in Fig. 2a).

A single impulsive sound signal becomes transformed into an N-wave (Fig. 2b) at large distances from its origin if the medium is quadratically nonlinear. Note that the integral of the time history of the function tends to zero as $x \rightarrow \infty$ as a result of diffraction.

In cubically nonlinear media the teeth of the saw blade have a trapezoidal form (Fig 2c). Each wave period has two shocks, one compression and the other rarefaction. The existence of sawtooth-shaped waves other than those shown in Fig. 2 is possible in media with more intricate nonlinear dissipative and dispersive behaviors. The disturbances shown in Fig. 2, however, are the most typical.

These effects shown in Fig. 2 can be explained using very simple physical arguments.¹¹ Theoretically, the wave motion in a fluid in which there is an infinitesimally small disturbance, which results in a sound pressure fluctuation field, p , can be described by the well-known wave equation:

$$\frac{\partial^2 p}{\partial x^2} - \frac{1}{c_0^2} \frac{\partial^2 p}{\partial t^2} = 0 \quad (1)$$

Theoretically, sound waves of infinitesimally small amplitude travel without distortion since all regions of the waveform have the same wave speed $dx/dt = c_0$. However, even in a lossless medium (one theoretically without the presence of dispersion), progressive waves of small but finite amplitude become distorted with distance and time. This is because, in the regions of the wave with positive sound pressure (and thus positive particle velocity), the sound wave travels faster than in the regions with negative sound pressure (and thus particle velocity). This effect is caused by two phenomena¹¹:

1. The sound wave is traveling through a velocity field consisting of the particle velocity u . So with waves of finite amplitude, the wave speed (with respect to a fixed frame of reference) is

$$dx/dt = c + u \quad (2)$$

where c is the speed of sound with respect to the fluid moving with velocity u .

2. The sound speed c is slightly different from the equilibrium sound speed c_0 . This is because where the particle velocity is positive (so is the sound pressure) the gas is compressed and the absolute temperature T is increased. Where the particle velocity is negative (and the sound pressure is too) then the temperature is decreased. An increased temperature results in a slightly higher sound speed c and a decreased temperature results in a slightly decreased sound speed c .

Mathematically we can show that the speed of sound is given by

$$c = c_0 + [(\gamma - 1)/2]u \quad (3)$$

where γ is the ratio of specific heats of the gas. We can also show that the deviation of c from c_0 can be related to the nonlinearity of the pressure-density relationship. If Eqs. (2) and (3) are combined, we obtain

$$dx/dt = c_0 + \beta u \quad (4)$$

where β is called the coefficient of nonlinearity and is given by

$$\beta = (\gamma + 1)/2 \quad (5)$$

The fact that the sound wave propagation speed depends on the local particle velocity as given by Eq. (4) shows that strong disturbances will travel faster than those of small magnitude and provides a simple demonstration of the essential nonlinearity of sound propagation.

We note in Fig. 3 that u_p is the particle velocity at the wave peak, and u_v is the particle velocity at the wave valley. The time used in the bottom figure of Fig. 3 is the retarded time $\tau = t - x/c_0$, which is used to present all of the waveforms together for comparison. The distance \bar{x} in Fig. 3c is the distance needed for the formation of a vertical wavefront.

Mathematically, nonlinear phenomena can be related to the presence of nonlinear terms in analytical models, for example, in wave equations. Physically, nonlinearity leads to a violation of the superposition principle, and waves start to interact with each other. As a result of the interaction between frequency components of the wave, new spectral regions appear and the wave energy is redistributed throughout the frequency spectrum. Nonlinear effects depend on the "strength" of the wave; they are well-defined if the intensity of the noise, the amplitude of the harmonic signal, or the peak pressure of a single pulse is large enough.

The interactions of intense noise waves can be studied by the use of statistical nonlinear acoustics.^{1,4,14,16} Such studies are important because different sources of high-intensity noise exist both in nature and engineering. Explosive waves in the atmosphere and in the ocean, acoustic shock pulses (sonic booms), noise generated by jets, and intense fluctuating sonar signals are examples of low-frequency disturbances for which nonlinear phenomena become significant at large distances. There also exist smaller noise sources whose spectra lie in the ultrasonic frequency range. These include, for instance, ordinary electromechanical transducers whose field always contains fluctuations, and microscopic sources like bubble (cavitation) noise and acoustic emission created during growth of cracks. Finally, intense noise of natural origin exists, such as thunder and seismic waves. There are obvious links between statistical nonlinear acoustics and "nonwave"

Figure 3 Wave steepening predicted by Eq. (4).²⁰

problems—turbulence, aeroacoustic interactions, and hydrodynamic instabilities.

3 BASIC MATHEMATICAL MODELS

3.1 Plane Waves

We shall start by considering the simple case of a plane progressive wave without the presence of reflections. For waves traveling only in the positive x direction, we have from Eq. (1), remembering that $p/u = \rho_0 c_0$,

$$\frac{\partial^2 u}{\partial x^2} - \frac{1}{c_0^2} \frac{\partial^2 u}{\partial t^2} = 0 \quad (6)$$

Equation (6) may be integrated once to yield a first-order wave equation:

$$\frac{\partial u}{\partial x} + \frac{1}{c_0} \frac{\partial u}{\partial t} = 0 \quad (7)$$

We note that the solution of the first-order Eq. (7) is $u = f(t - x/c_0)$, where f is any function. Equation (7) can also be simplified further by transforming it from the coordinates x and t to the coordinates x and τ , where $\tau = t - x/c_0$ is the so-called retarded time. This most simple form of equation for a linear traveling wave is $\partial u(x, \tau)/\partial x = 0$. This form is equivalent to the form of Eq. (7).

The model equation containing an additional nonlinear term that describes source-generated waves of

finite amplitude in a lossless fluid is known as the Riemann wave equation:

$$\frac{\partial u}{\partial x} - \frac{\beta}{c_0^2} u \frac{\partial u}{\partial \tau} = 0 \quad (8)$$

Physically, its general solution is $u = f(\tau + \beta u x / c_0^2)$.

For sinusoidal source excitation, $u = u_0 \sin(\omega t)$ at $x = 0$, the solution is represented by the Fubini series^{1,2}:

$$\frac{u}{u_0} = \sum_{n=1}^{\infty} \frac{2}{n z} J_n(n z) \sin(n \omega \tau) \quad (9)$$

Here $z = x/\bar{x}$ is the normalized coordinate (see Fig. 3), and $\bar{x} = c_0^2/(\beta \omega u_0)$ is the shock formation distance. As shown in Fig. 4, at the distance $z = 1$, or at $x = \bar{x}$, the amplitude of the second and third harmonics reach correspondingly 0.35 and 0.2 of the initial amplitude of the fundamental harmonic. Consequently, at distances $x \approx \bar{x}$ nonlinearity comes into particular prominence.

For example, if an ultrasonic wave having an intensity of 10 W/cm² and a frequency of 1 MHz propagates in water ($\beta \approx 4$), the shock formation distance is about 25 cm. For a sound wave propagating in the air ($\beta \approx 1.2$) and having a sound pressure level of 140 dB (relative to the root-mean-square pressure

Figure 4 Schematic of energy "pumping" to higher frequencies predicted by the Fubini solution.

2×10^{-5} Pa) and at a frequency 3.3 kHz, one can estimate that $\bar{x} \approx 6$ m.

Many of the physical phenomena accompanying high-intensity wave propagation can compete with the

nonlinearity and weaken its effect. Phenomena such as dissipation, diffraction, reflection, and scattering decrease the characteristic amplitude u_0 of the initial wave and, consequently, increase the shock formation distance \bar{x} . The influence of dissipation can be evaluated by use of an inverse acoustical Reynolds number $\Gamma = \alpha \bar{x}$,¹ where α is the normal absorption coefficient of a linear wave. Numerical studies (Rudenko²³) show that nonlinearity is clearly observed at $\Gamma \leq 0.1$. The absorption predominates at high values of Γ , and nonlinear transformation of the temporal profile and spectrum is weak. For two examples given above, the parameter Γ is equal to 0.0057 (water) and 0.0014 (air), and conditions to observe nonlinear distortion are very good.

The competition between nonlinearity and absorption is shown in Fig. 5. In the first stage, for distances $x < \bar{x}$, the distortion of the initial harmonic wave profile goes on in accordance with the Fubini solution [Eq. (9)]. Thereafter, during the second stage, $\bar{x} < x < 2/\alpha$, a leading steep shock front forms inside each wavelength, and the wave profile takes on a sawtooth-shaped form. The nonlinear absorption leads to the decay of the peak disturbance, and after considerable energy loss has occurred, at distances $x > 2/\alpha$, the wave profile becomes harmonic again. So, in this third stage $x > 2/\alpha$, the propagation of the impaired wave is described by the linear wave equation.

Figure 5 Transformation of one period of harmonic initial signal in the nonlinear and dissipative medium.²³ Normalized variables are used here: $V = u/u_0$ and $Z = x/\bar{x}$.

3.2 General Wave Equation for Nonlinear Wave Propagation

The general equation that describes one-dimensional propagation of a nonlinear wave is

$$\frac{\partial p}{\partial x} + \frac{p}{2} \frac{d}{dx} \ln S(x) - \frac{\beta}{c_0^3 \rho_0} p \frac{\partial p}{\partial \tau} - \frac{b}{2c_0^3 \rho_0} \frac{\partial^2 p}{\partial \tau^2} = 0 \quad (10)$$

Here $p(x, \tau)$ is the acoustic pressure, which depends on the distance x and the retarded time $\tau = t - x/c_0$, which is measured in the coordinate system accompanying the wave and moves with the sound velocity c_0 ; β , b are coefficients of nonlinearity and effective viscosity,¹ and ρ_0 is the equilibrium density of the medium. Equation (1) can describe waves traveling in horns or concentrators having a cross-section area $S(x)$. If $S = \text{const}$, Eq. (10) transforms to the ordinary Burgers equation for plane waves.¹ If $S \sim x$, Eq. (10) describes cylindrical waves, and if $S \sim x^2$, it describes spherical ones. Equation (10) is applicable also as a transfer equation to describe waves propagating through media with large inhomogeneities if a nonlinear geometrical approach is used; for such problems, $S(x)$ is the cross-section area of the ray tube, and the distance x is measured along the central curvilinear ray. Using new variables

$$V = \frac{p}{p_0} \sqrt{\frac{S(x)}{S(0)}} \quad \theta = \omega_0 \tau,$$

$$z = \omega_0 p_0 \int_0^x \frac{\beta}{c_0^3 \rho_0} \sqrt{\frac{S(0)}{S(x')}} dx'$$

one can reduce Eq. (10) to the generalized Burgers equation

$$\frac{\partial V}{\partial z} - V \frac{\partial V}{\partial \theta} = \Gamma(z) \frac{\partial^2 V}{\partial \theta^2} \quad (11)$$

whose properties are described in the literature.^{1,17} Here p_0 and ω_0 are typical magnitudes of the initial acoustic pressure and frequency, and

$$\Gamma(z) = \left[\frac{b\omega_0}{2\beta p_0} \sqrt{\frac{S(x)}{S(0)}} \right]_{x=x(z)} \quad (12)$$

is the normalized effective viscosity.

Next a one-dimensional model can be derived to describe nonlinear waves in a hereditary medium (i.e., a medium with a memory)¹:

$$\frac{\partial p}{\partial x} - \frac{\beta}{c_0^3 \rho_0} p \frac{\partial p}{\partial \tau} - \frac{m}{2c_0} \frac{\partial}{\partial \tau} \int_{-\infty}^{\tau} K(\tau - \tau') \frac{\partial p}{\partial \tau'} d\tau' = 0 \quad (13)$$

Here m is a constant that characterizes the “strength of memory,” and the kernel $K(t)$ is a decaying function that describes the temporal weakening of the memory. In relaxing fluids $K(t) = \exp(-t/t_r)$, where t_r is the relaxation time. Such an exponential kernel is valid for atmospheric gases; it leads to the appearance of dispersion and additional absorption, which is responsible for shock front broadening during the propagation of a sonic boom. For solids, reinforced plastics and biological tissues $K(t)$ has a more complicated form.

If it is necessary to describe the behavior of acoustical beams and to account for diffraction phenomena, the following equation can be used:

$$\frac{\partial}{\partial \tau} [\hat{\Pi}(p)] = \frac{c_0}{2} \Delta_{\perp} p \quad (14)$$

where Δ_{\perp} is the “transverse” Laplace operator acting on coordinates in the cross section of the acoustical beam; $\hat{\Pi}(p) = 0$ is one of the one-dimensional equations that is to be generalized [e.g. Eqs. (10) or (13)]. The Khokhlov–Zabolotskaya–Kuznetsov Eq. (15)^{5,9}:

$$\frac{\partial}{\partial \tau} \left[\frac{\partial p}{\partial x} - \frac{\beta}{c_0^3 \rho_0} p \frac{\partial p}{\partial \tau} - \frac{b}{2c_0^3 \rho_0} \frac{\partial^2 p}{\partial \tau^2} \right] = \frac{c_0}{2} \Delta_{\perp} p \quad (15)$$

is the most well-known example; it generalizes the Burgers equation for beams and takes into account diffraction, in addition to nonlinearity and absorption.

4 NONLINEAR TRANSFORMATION OF NOISE SPECTRA

The following are examples and results obtained from numerical or analytical solutions to the models listed above. All tendencies described below have been observed in laboratory experiments or in full-scale measurements, for example, jet and rocket noise (see details in the literature^{1,14,16}).

4.1 Narrow-Band Noise

Initially, a randomly modulated quasi-harmonic signal generates higher harmonics $n\omega_0$, where ω_0 is the fundamental frequency. At short distances in a Gaussian noise field the mean intensity of the n th harmonic is $n!$ times higher than the intensity of the n th harmonic of a regular wave. This phenomenon is related to the dominating influence of high-intensity spikes caused by nonlinear wave transformations. The characteristic width of the spectral line of the n th harmonic increases with increases in both the harmonic number n and the distance of propagation x .

4.2 Broadband Noise

During the propagation of the initial broadband noise (a segment of the temporal profile of the waveform is shown by curve 1 in Fig. 6a) continuous distortion occurs. Curves 2 and 3 are constructed for successively

Figure 6 (a) Nonlinear distortion of a segment of the temporal profile of initial broadband noise p . Curves 1, 2, and 3 correspond to increasing distances $x_1 = 0, x_2 > 0, x_3 > x_2$. (b) Nonlinear distortion of the spectrum $G(\omega, x)$ of broadband noise. Curves 1, 2, and 3 correspond to the temporal profiles shown in (a).

increasing distance and display two main tendencies. The first one is the steepening of the leading fronts and the formation of shock waves; it produces a broadening of the spectrum toward the high-frequency region.

The second tendency is a spreading out of the shocks, collisions of pairs of them and their joining together; these processes are similar to the adhesion of absolutely inelastic particles and lead to energy flow into the low-frequency region.

Nonlinear processes of energy redistribution are shown in Fig. 6b. Curves 1, 2, and 3 in Fig. 6b are the mean intensity spectra $G(\omega, x)$ of random noise waves 1, 2, and 3 whose retarded time histories are shown in Fig. 6a.

The general statistical solution of Eq. (10), which describes the transformation of high-intensity noise spectra in a nondissipative medium, is known for $b = 0^1$:

$$G(\omega, x) = \frac{\exp\left[-\left(\frac{\varepsilon}{c_0^3 \rho_0} \omega \sigma x\right)^2\right]}{2\pi \left(\frac{\varepsilon}{c_0^3 \rho_0} \omega \sigma x\right)^2} \times \int_{-\infty}^{\infty} \left\{ \exp\left[\left(\frac{\varepsilon}{c_0^3 \rho_0} \omega x\right)^2 R(\theta)\right] - 1 \right\} \times \exp(-i\omega\theta) d\theta \quad (16)$$

Here $R(\theta = \theta_1 - \theta_2) = \langle p(\theta_1)p(\theta_2) \rangle$ is the correlation function of an initial stationary and Gaussian random

process, and $\sigma^2 = R(0)$. For simplicity, the solution, Eq. (16), is written here for plane waves; but one can easily generalize it for arbitrary one-dimensional waves [for any cross-section area $S(x)$] using the transformation of variables. See Eq. (12).

4.3 Noise-Signal Interactions

The initial spectrum shown in Fig. 7a consists of a spectral line of a pure tone harmonic signal and broadband noise. The spectrum, after distortion by nonlinear effects, is shown in Fig. 7b.

As a result of the interaction, the intensity of the fundamental pure tone wave ω_0 is decreased, due to the transfer of energy into the noise component and because of the generation of the higher harmonics, $n\omega_0$. New spectral wave noise components appear in the vicinity $\omega = n\omega_0$, where $n = 1, 2, 3, \dots$. These noise components grow rapidly during the wave propagation, flow together, and form the continuous part of the spectrum (see Fig. 7b).

In addition to being intensified, the noise spectrum can also be somewhat suppressed. To observe this phenomenon, it is necessary to irradiate noise with an intense signal whose frequency is high enough so that the initial noise spectrum, and the noise component generated near to the first harmonic, do not overlap.¹⁴

Weak high-frequency noise can be also partly suppressed due to nonlinear modulation by high-intensity low-frequency regular waves. Some possibilities for the control of nonlinear intense noise are described in the literature.^{8,14}

The attenuation of a weak harmonic signal due to nonlinear interaction with a noise wave propagating in the same direction occurs according to the law

$$p = p_0 \exp\left[-\frac{1}{2} \left(\frac{\varepsilon}{c_0^3 \rho_0} \omega_0 \sigma x\right)^2\right] \quad (17)$$

Figure 7 Nonlinear interaction of spectra of the tone signal and broadband noise. Initial spectrum (a) corresponds to the distance $x = 0$. Spectrum (b) measured at the distance $x > 0$ consists of higher harmonics $n\omega_0$ and new broadband spectral areas.

here $\sigma^2 = \langle p^2 \rangle$ is the mean noise intensity. The dependence of the absorption with distance x in Eq. (17) is given by $\exp(-\beta x^2)$, which does not depend on either the location of the noise or the signal spectrum. The standard dependence $\exp(-\alpha x)$ takes place if a deterministic harmonic signal propagates in a spatially isotropic noise field. Here²¹

$$\alpha = \frac{\pi \varepsilon^2}{4 c_0^5 \rho_0^2} \left[\int_0^{\omega_0} \frac{\omega_0^2 + \omega^2}{\omega} G(\omega) d\omega + 2\omega_0 \int_{\omega_0}^{\infty} G(\omega) d\omega \right] \quad (18)$$

where $G(\omega)$ is the spectrum of the noise intensity:

$$\sigma^2 = \int_0^{\infty} G(\omega) d\omega$$

5 TRANSFORMATION OF STATISTICAL DISTRIBUTION

The nonlinear distortion of the probability distribution for nonlinear quasi-harmonic noise is illustrated in Fig. 8. Curve 1 shows the initial Gaussian distribution. Because of shock wave formation and subsequent nonlinear absorption, the probability of small values of the acoustic pressure p increases owing to the decrease in the probability of large high-peak pressure jumps (curves 2 and 3).

A regular signal passing through a random medium gains statistical properties. Typical examples are connected with underwater and atmospheric long-range propagation, as well as with medical devices using shock pulses and nonlinear ultrasound in such an inhomogeneous medium as the human body.

A sonic boom (N-wave) generated by a supersonic aircraft propagates through the turbulent boundary

Figure 8 Nonlinear distortion of the probability of detection $W(p)$ of the given value of acoustic pressure p . Curves 1, 2, and 3 correspond to increasing distances $x_1 = 0, x_2 > 0$, and $x_3 > x_2$.

Figure 9 Nonlinear distortion of the statistical distribution of the peak pressure of a sonic boom wave passed through a turbulent layer. Line 1 is the initial distribution, curves 2 and 3 correspond to distances $x_1, x_2 > x_1$.

layers of the atmosphere. Transformation of the statistical distribution of its peak pressure is shown in Fig. 9.¹⁸ Initial distribution is a delta-function (line 1), peak pressure is pre-determined and is equal to p_0 .

At increasing distances (after passing through the turbulent layer, curves 2 and 3), this distribution broadens; the probability increases that both small- and large-amplitude outbursts are observed. So, turbulence leads to a decrease in the mean peak pressure, but fluctuations increase as a result of random focusing and defocusing caused by the random inhomogeneities in the atmosphere.

Nonlinear propagation in media containing small inhomogeneities responsible for wave scattering is governed by an equation like Eq. (10), but one which contains a fourth-order dissipative term instead of a second-order one¹⁹:

$$-\frac{b}{2c_0^3 \rho_0} \frac{\partial^2 p}{\partial \tau^2} \Rightarrow +\beta \frac{\partial^4 p}{\partial \tau^4} \quad \beta = \frac{8\langle \mu^2 \rangle a^3}{c_0^4} \quad (19)$$

Here $\langle \mu^2 \rangle$ is the mean square of fluctuations of the refractive index, and a is the radius of correlation. Scattering losses are proportional to ω^4 instead of ω^2 in viscous media. Such dependence has an influence on the temporal profile and the spectrum of the nonlinear wave; in particular, the increase of pressure at the shock front has a nonmonotonic (oscillatory) character.

6 SAMPLE PRACTICAL CALCULATIONS

It is of interest in practice to consider the parameter values for which the nonlinear phenomena discussed above are physically significant. For instance, in measuring the exhaust noise of a commercial airliner or of a spacecraft rocket engine at distances of 100 to 200 m, is it necessary to consider nonlinear spectral distortion or not? To answer this question we evaluate the shock formation distance for wave propagation in air in more detail than in Section 3.

For a plane simple harmonic wave, the shock formation distance is equal to

$$\bar{x}_{\text{pl}} = \frac{c_0^2}{\beta \omega u_0} = \frac{c_0^3 \rho_0}{2\pi \beta f p_0} \quad (20)$$

where p_0 is the amplitude of the sound pressure, and $f = \omega/2\pi$ is the frequency. For a spherical wave one can derive the shock formation distance using Eqs. (10) and (11):

$$\bar{x}_{\text{sph}} = x_0 \exp\left(\frac{c_0^3 \rho_0}{2\pi \beta f p_0 x_0}\right) \quad (21)$$

Here x_0 is the radius of the initial spherical front of the diverging wave. In other words, x_0 is the radius of a spherical surface surrounding the source of intense noise, at which the initial wave shape or spectrum is measured.

Let the sound pressure level of the noise measured at a distance of $x_0 = 10$ m be 140 dB, and the typical peak frequency f of the spectrum be 1 kHz. Evaluating the situation for propagation in air using the parameters:

$$\beta = 1.2 \quad c_0 = 330 \text{ m/s} \quad \rho_0 = 1.3 \text{ kg/m}^3$$

gives the following values for the shock formation distances:

$$\bar{x}_{\text{pl}} \sim 20 \text{ m} \quad \bar{x}_{\text{sph}} \sim 80 \text{ m}$$

So in this situation, shocks form in spherical wave propagation at a greater distance than in plane wave propagation because the spherical spreading decreases the wave intensity and, consequently, nonlinear phenomena accumulate more slowly in the spherical than in the plane wave propagation case.

In all practical cases, the real shock front formation length \bar{x} obeys the inequality

$$\bar{x}_{\text{pl}} < \bar{x} < \bar{x}_{\text{sph}}$$

At distances, for which $x \sim \bar{x}$, nonlinear distortion is significant.

During experiments performed by Pestorius and Blackstock,²⁵ which used a long tube filled with air, strong nonlinear distortion of the noise spectrum was observed at distances between as little as 2 to 10 m, for sound pressure levels of 160 dB. This result agrees with predictions made using Eq. (20) for a frequency f of about 1 kHz. Morfey²⁶ analyzed several experiments and observed nonlinear distortion in the spectra of four-engine jet aircraft at distances between 262 and 501 m, for frequencies between $f = 2$ and 10 kHz. He also analyzed the noise spectrum of an Atlas-D rocket engine at distances of 1250 to 5257 m, at frequencies in the range of $f = 0.3$ to 2.4 kHz. These observations correspond to the

analytical case of spherically diverging waves. See Eq. (21).

Extremely strong noise is produced near the rocket exhausts of large spacecraft during launch. For example, assume that the sound pressure level is 170 dB at 10 m from a powerful space vehicle such as the *Saturn V* or the space shuttle. The shock formation distance is predicted from Eq. (21) to be a further distance of $\bar{x}_{\text{sph}} \approx 13$ m for a frequency of 500 Hz. The approximate temporal duration t_{fr} of the shock front at a distance x can be calculated using Eq. (22), which is found in Rudenko and Soluyan¹:

$$t_{\text{fr}} = \frac{1}{\pi^2 f} \frac{\bar{x}_{\text{pl}}}{\bar{x}_{\text{abs}}} \frac{x}{x_0} \left[1 + \frac{x_0}{\bar{x}_{\text{pl}}} \ln\left(\frac{x}{x_0}\right) \right] \quad (22)$$

where $\bar{x}_{\text{abs}} = \alpha^{-1} = (4\pi^2 f^2 \delta)^{-1}$ is the absorption length, and the value of $\delta = 0.5 \times 10^{-12} \text{ s}^2/\text{m}$ is assumed for air. For the assumed sound pressure level of 170 dB and the frequency 500 Hz, we substitute the values $\bar{x}_{\text{pl}} = x_0 = 10$ m and evaluate the width of the shock front $l_{\text{fr}} = c_0 t_{\text{fr}}$ at small distances of 25 to 30 m from the center of the rocket exhaust nozzles. This shock width being of the order of $l_{\text{fr}} \approx 0.01 - 0.1$ mm is much less than the wavelength, $\lambda \approx 67$ cm. Such a steep shock front is formed because of strong nonlinear effects. As the sound wave propagates, the shock width increases and reaches $l_{\text{fr}} \approx 7$ cm at distances of about 23 km. It is evident that nonlinear phenomena will be experienced at large distances from the rocket. That is the reason why it is possible to hear the "crackling sound" standing far from the launch position. However, the value of 23 km for the distance at which the shock disappears is realistic only if the atmosphere is assumed to be an unlimited and homogeneous medium. In reality, due to reflection from the ground and the refraction of sound rays in the real inhomogeneous atmosphere, the audibility range for shocks can be somewhat less. To describe nonlinear sound propagation in the real atmosphere, the numerical solution of the analysis of more complicated mathematical models such as Rudenko²² needs to be undertaken.

It is necessary to draw attention to the strong exponential dependence of nonlinear effects on the frequency f_0 , the sound wave amplitude p_0 , and the initial propagation radius x_0 , for spherical waves. From Eq. (21) we have

$$\bar{x}_{\text{sph}} = x_0 \exp\left(\frac{\text{const}}{f p_0 x_0}\right)$$

Consequently, the shock formation distance \bar{x}_{sph} is very sensitive to the accuracy of measurement of these parameters. Other numerical examples concerning nonlinear noise control are given in the literature.^{8,14,16}

Consider now a sonic boom wave propagating as a cylindrical diverging wave from a supersonic aircraft.

The shock formation distance for this case is

$$\bar{x}_{\text{cyl}} = x_0 \left(1 + \frac{c_0^3 \rho_0}{4\pi \beta f p_0 x_0} \right)^2 \quad (23)$$

At small distances from the aircraft, for example, at 50 m, the peak sound pressure is about 3000 Pa and the pulse duration $t_0 = f^{-1} \sim l/v$, where l is the length of the aircraft fuselage, and $v > c_0$ is the speed of supersonic flight. For the parameters of aircraft length and speed, $l = 10$ m, $v = 1.3c_0$, evaluation of Eq. (23) gives $\bar{x}_{\text{cyl}} \sim 100$ m. This means that at several hundred metres from the aircraft, the multiple collisions of shocks generated by singularities of the aerodynamic profile come to an end, and the sonic boom wave changes into an N-wave, as shown in Fig. 2b.

At greater distances, the peak pressure of the N-wave decreases, and the value of the distance \bar{x}_{cyl} increases. For a peak pressure of 200 Pa measured at $x_0 = 1$ km, and for a pulse duration $t_0 = f^{-1} = 0.05$ s we obtain a distance of $\bar{x}_{\text{cyl}} \sim 3$ km, according to Eq. (23). So, for a distance of $x_0 = 1$ km from the aircraft, an additional distance $\bar{x}_{\text{cyl}} - x_0 = 2$ km will produce a significant change in the shape of the N-wave due to the nonlinear wave propagation effects.

Nonlinear phenomena appear also near to the sharp tips of bodies and orifices in the high-speed streamlines of an oscillating fluid. These nonlinearities are caused by the large spatial gradients in the hydrodynamic field and are related to the convective term $(\mathbf{u} \nabla) \mathbf{u}$ in the equation of motion of the fluid, in the form of the Navier–Stokes or Euler equations. This effect is quite distinct from the more common nonlinear phenomena already described. Nonlinear wave distortion cannot build up during wave propagation since the effect only has a “local” character. To determine the necessary sound pressure level at which we can observe these phenomena in an oscillating flow, we evaluate the velocity gradients. (Note that in the case of harmonic vibrations in the streamlines around an incompressible liquid, higher harmonics will appear.) We assume that the gradient is of the order of $u / \max(r_0, \delta)$, where $\delta = \sqrt{\nu/\omega}$ is the width of the acoustical boundary layer, r_0 is the minimum radius of the edge of the body, u is the vibration velocity, and $\nu = \eta/\rho_0$ is the kinematic viscosity. The width is the dominating factor for sharp edges, if $r_0 < \delta$. This “boundary nonlinearity” is significant at Reynolds numbers of $\text{Re} \sim 1$, which are proportional to the ratio of the terms in the Navier–Stokes or Euler equations of motion of the fluid:

$$\text{Re} \sim \left| (\mathbf{u} \nabla) \mathbf{u} \left(\frac{\partial \mathbf{u}}{\partial t} \right)^{-1} \right| \sim \frac{u}{\sqrt{\omega \nu}} = \sqrt{\frac{2I}{c\omega\eta}} \quad (24)$$

As can be determined by Eq. (24), this nonlinearity manifests itself in air at a sound pressure level of 120 dB, at a frequency of about 500 Hz. If vortices form near to the edge of a body immersed in an oscillating flow, nonlinearity in such a flow can be

observed even at a sound pressure level as low as 90 dB. Boundary layer nonlinearity is significant in the determination of the resonance frequency of sound absorbers, which contain Helmholtz resonators with sound-absorbing material in their necks. This nonlinearity can detune the resonance condition at the frequency given by linear approximations. It can even have the opposite effect of enhancing the dissipation of acoustic energy by the absorber, if it is excited off resonance, according to the linear approximations.⁸

7 FURTHER COMMENTS AND CONCLUSIONS

Only common nonlinear events occurring in typical media have been discussed. However, nonlinear phenomena of much more variety can occur. Nonlinearity manifests itself markedly in conditions of resonance, if the standing waves that form in spatially limited systems have a high Q factor. Using high- Q resonators, it is possible to accumulate a considerable amount of acoustic energy and provide conditions for the clear manifestation of nonlinear phenomena even in the case of weak sound sources.²³

Some structures (such as components of the fuselage of an aircraft) can have huge nonlinearities caused by special types of inhomogeneous inclusions (in cases such as the delamination of layered composites, with cracks and grain boundaries in metals, and with clamped or impacting parts, etc.). These nonlinear phenomena can be used to advantage in sensitive nondestructive tests.

It is necessary to mention a nonlinear device known as a “parametric array.” Its use is common in underwater acoustics.⁹ Recently, it has also been put to use in air in the design of parametric loudspeakers.^{27,28}

The difference between linear and nonlinear problems is sometimes only relative. For example, aerodynamic sound generation can be referred to as a linear problem; but some people say that this is a nonlinear phenomenon described by the nonlinear terms in the Lighthill equation. Both viewpoints are true. Chapter 9 in this book, which is written by Morris and Lilley, is devoted to the subject of aerodynamic sound. The aerodynamic exhaust noise generated by turbojet and turbofan engines is discussed by Huff and Envia in Chapter 89 of this book. Lighthill, Powell and Ffowcs Williams also discuss jet noise generation in Chapters 24, 25, and 26 in the *Handbook of Acoustics*.²⁹

CHAPTER 9

AERODYNAMIC NOISE: THEORY AND APPLICATIONS

Philip J. Morris and Geoffrey M. Lilley*
Department of Aerospace Engineering
Pennsylvania State University
University Park, Pennsylvania

1 INTRODUCTION

This chapter provides an overview of *aerodynamic noise*. The theory of aerodynamic noise, founded by Sir James Lighthill,¹ embraces the disciplines of acoustics and unsteady aerodynamics, including turbulent flow. Aerodynamic noise is generated by the unsteady, nonlinear, turbulent flow. Thus, it is self-generated rather than being the response to an externally imposed source. It is sometimes referred to as *flow noise*, as, for instance, in duct acoustics, and is also related to the theory of hydrodynamic noise. In its applications to aeronautical problems we will often mention *aeroacoustics* in referring to problems of both sound propagation and generation. The source of aerodynamic noise is often a *turbulent flow*. So some description of the characteristics of turbulence in jets, mixing regions, wakes, and boundary layers will give the reader sufficient information on the properties of turbulent flows relevant to noise prediction.

2 BACKGROUND

In 1957, Henning von Gierke² wrote:

Jet aircraft, predominating with military aviation, create one of the most powerful sources of man-made sound, which by far exceeds the noise power of conventional propeller engines. The sound [pressure] levels around jet engines, where personnel must work efficiently, have risen to a point where they are a hazard to man's health and safety and are now at the limit of human tolerance. Further increase of sound [pressure] levels should not be made without adequate protection and control; technical and operational solutions must be found to the noise problem if it is not to be a serious impediment to further progress in aviation.

In spite of tremendous progress in the reduction of aircraft engine noise (see Chapters 89 and 90 of this handbook), the issues referred to by von Gierke continue to exist. Aircraft noise at takeoff remains an engine noise problem. However, for modern commercial aircraft powered by high bypass ratio

turbofan engines, during the low-level approach path of all aircraft to landing, it is found that engine and airframe make almost equal contributions to the total aircraft noise as heard in residential communities close to all airports. Thus, the physical understanding of both aircraft engine and airframe noise, together with their prediction and control, remain important challenges in the overall control of environmental pollution.

In this chapter, following a brief introduction into the theory of linear and nonlinear acoustics, the general theory of aerodynamic noise is presented. The discussion is then divided between the applications of the theory of Lighthill^{1,3} to the noise generation of free turbulent flows, such as the mixing region noise of a jet at subsonic and supersonic speeds, and its extension by Curle,⁴ referred to as the theory of Lighthill–Curle, to the noise generation from aircraft and other bodies in motion. The other major development of Lighthill's theory, which is discussed in this chapter, is its solution due to Ffowcs Williams and Hawkings⁵ for arbitrary surfaces in motion. Lighthill's theory as originally developed considered the effects of convective amplification, which was later extended to include transonic and supersonic jet Mach numbers by Ffowcs Williams.⁶ It is referred to as the Lighthill–Ffowcs Williams *convective amplification theory*. In its application, Lighthill's theory neglects any interaction between the turbulent flow and the sound field generated by it. The extension of Lighthill's theory to include *flow-acoustical interaction* was due to Lilley.⁷ This is also described in this chapter, along with a more general treatment of its practical application, using the linearized Euler equations with the nonlinear sources similar to those found in Lighthill's theory, and the adjoint method due to Tam and Auriault.⁸

In the discussion on the applications to *jet noise*, the noise arising from turbulent mixing is shown to be enhanced at supersonic speeds by the presence of a shock and expansion cell structure in the region of the jet potential core. This results in both broadband shock associated noise and tonal components called screech. The noise sources revert to those associated with turbulent mixing only downstream of the station where the flow velocity on the jet axis has decayed to the local sonic velocity.

The practical application of the combined theory of generation and propagation of aerodynamic noise is introduced in Section 8, which discusses *computational aeroacoustics* (CAA). This relatively new

field uses the computational power of modern high-performance computers to simulate both the turbulent flow and the noise it generates and radiates.

The final sections of this chapter consider applications of aerodynamic noise theory to the noise radiated from turbulent boundary layers developing over the wings of aircraft and their control surfaces. The two major developments in this field are the Lighthill–Curle⁴ theory applicable to solid bodies and the more general theory due to Ffowcs Williams and Hawkings⁵ for arbitrary surfaces in motion. The theory has applications to the noise from closed bodies in motion at sufficiently high Reynolds numbers for the boundary layers to be turbulent. The theory applies to both attached and separated boundary layers around bluff bodies and aircraft wings at high lift. Noise radiation is absent from steady laminar boundary layers but strong noise radiation occurs from the unsteady flow in the transition region between laminar and turbulent flow. A further important aspect of the noise from bodies in motion is the diffraction of sound that occurs at a wing trailing edge. The theory of *trailing edge noise* involves a further extension of Lighthill's theory and was introduced by Ffowcs Williams and Hall.⁹ In aeronautics today, one of the major applications of *boundary layer noise* is the prediction and reduction of noise generated by the airframe, which includes the wings, control surfaces, and the undercarriage. This subject is known as *airframe noise*. Its theory is discussed with relevant results together with brief references to methods of noise control.

Throughout the chapter simple descriptions of the physical processes involving noise generation from turbulent flows are given along with elementary scaling laws. Wherever possible, detailed analysis is omitted, although some analysis is unavoidable. A comprehensive list of references has been provided to assist the interested reader. In addition, there are several books that cover the general areas of acoustics and aeroacoustics. These include, Goldstein,¹⁰ Lighthill,¹¹ Pierce,¹² Dowling and Ffowcs Williams,¹³ Hubbard,¹⁴ Crighton et al.,¹⁵ and Howe.¹⁶ Additional reviews are contained in Ribner,¹⁷ and Crocker.^{18,19} In this chapter we do not discuss problems where aerodynamic noise is influenced by the vibration of solid surfaces, such as in fluid–structure interactions, where reference should be made to Cremer, Heckl, and Petersson²⁰ and Howe.¹⁶

3 DIFFERENCES BETWEEN AERODYNAMIC NOISE AND LINEAR AND NONLINEAR ACOUSTICS

The theory of linear acoustics is based on the linearization of the Navier–Stokes equations for an inviscid and isentropic flow in which the propagation of weak acoustic waves are small perturbations on the fluid at rest. The circular frequency, ω , of the acoustic, or sound, waves is given by

$$\omega = kc \quad (1)$$

where $k = 2\pi/\lambda$ is the wavenumber, λ is the acoustic wavelength, and c is the speed of sound. The frequency in hertz, $f = \omega/2\pi$. Linear acoustics uses the linearized Euler equations, derived from the Navier–Stokes equations, incorporating the thermodynamic properties of a perfect gas at rest. The properties of the undisturbed fluid at rest are defined by the subscript zero and involve the density ρ_0 , pressure p_0 , and enthalpy h_0 , with $p_0 = \rho_0 h_0(\gamma - 1)/\gamma$, and the speed of sound squared, $c_0^2 = \gamma p_0/\rho_0 = (\gamma - 1)h_0$. The relevant perturbation conservation equations of mass and momentum for a fluid at rest are, respectively,

$$\frac{\partial \rho'}{\partial t} + \rho_0 \theta' = 0 \quad \frac{\partial \rho_0 \mathbf{v}'}{\partial t} + \nabla p' = 0 \quad (2)$$

where $\theta' = \nabla \cdot \mathbf{v}'$ is the fluctuation in the rate of dilatation, and \mathbf{v}' is the acoustic particle velocity. In the propagation of plane waves $p' = \rho_0 c_0 v'$. Since the flow is isentropic $p' = c_0^2 \rho'$.

From these governing equations of linearized acoustics we find, on elimination of θ' , the *unique* acoustic wave equation for a fluid at rest, namely

$$\left(\frac{\partial^2}{\partial t^2} - c_0^2 \nabla^2 \right) \rho' = 0 \quad (3)$$

When the background fluid is in motion, with the uniform velocity \mathbf{V}_0 , the linear operator following the motion is $D_0/Dt \equiv \partial/\partial t + \mathbf{V}_0 \cdot \nabla$, and we obtain the *Galilean invariant* convected acoustic wave equation,

$$\left(\frac{D_0^2}{Dt^2} - c_0^2 \nabla^2 \right) \rho' = 0 \quad (4)$$

Problems in acoustics can be solved by introducing both volume and surface distributions of sound sources, which are classified by type as monopole, dipole, quadrupole, and so on, representing, respectively, a single simple source, and two and four simple sources in close proximity, and are similar to the point sources in ideal potential flow fluid dynamics. The inhomogeneous acoustic wave equations are obtained by adding the distribution of acoustic sources, $A(\mathbf{x}, t)$, to form the right-hand side of the homogeneous convection equation (4):

$$\left(\frac{D_0^2}{Dt^2} - c_0^2 \nabla^2 \right) \rho' = A(\mathbf{x}, t) \quad (5)$$

and similarly for the unique wave equation (3).

The energy conservation equation is obtained by multiplying, respectively, the above conservation of mass and momentum equations by p' and \mathbf{v}' to give

$$\begin{aligned} \frac{1}{2\rho_0 c_0^2} \frac{\partial (p')^2}{\partial t} &= -\theta' p' \\ \frac{\partial \rho_0 (v')^2/2}{\partial t} &= -\nabla \cdot p' \mathbf{v}' + \theta' p' \end{aligned} \quad (6)$$

By elimination of $p'\theta'$ we find the energy conservation equation in linear acoustics, namely

$$\frac{\partial w}{\partial t} + \nabla \cdot \mathbf{I} = 0 \quad (7)$$

where $w = \rho_0(v')^2/2 + (\frac{1}{2})(p')^2/(\rho_0 c_0^2)$ is the sum of the acoustic kinetic and potential energies and $\mathbf{I} = p'\mathbf{v}'$ is the acoustic intensity.

When the acoustic waves are of finite amplitude, we must use the complete Navier–Stokes equations. However, on the assumption that the diffusive terms have negligible influence on wave propagation at high Reynolds numbers, we find that for acoustic waves of finite amplitude propagating in one dimension only, the following exact nonlinear inhomogeneous acoustic wave equation can be obtained:

$$\frac{D^2 \chi}{Dt^2} - \frac{\partial}{\partial x} \left(c^2 \frac{\partial \chi}{\partial x} \right) - \left(\frac{D\chi}{Dt} \right)^2 = 0 \quad (8)$$

where $\chi = \ln \rho/\rho_0$, $D/Dt \equiv \partial/\partial t + u\partial/\partial x$ is the nonlinear convective operator following the motion, and the variable sound speed $c^2 = c_0^2 \exp[(\gamma - 1)\chi]$. The nonlinearity is shown by the addition of $(D\chi/Dt)^2$ to the linear acoustic wave equation, together with the dependence of the speed of sound on the amplitude χ . Problems in nonlinear acoustics require the solution of the corresponding nonlinear inhomogeneous equation incorporating the distribution of acoustic source multipoles on the right-hand side of the above homogeneous equation. A simpler approach is to use the Lighthill–Whitham²¹ theory whereby the linear acoustical solution is obtained and then its characteristics are modified to include the effects of the finite amplitude wave motion and the consequent changes in the sound speed. It is also found from the Navier–Stokes equations, including the viscous terms, that in one dimension, and using the equation for χ , the nonlinear equation for the particle velocity, u , is given approximately, due to the vanishingly small rate of dilatation inside the flow, by Burgers equation,

$$\frac{Du}{Dt} = \nu \nabla^2 u \quad (9)$$

which explains the nonlinear steepening arising in the wave propagation plus its viscous broadening. It has an exact solution based on the Cole–Hopf transformation. The fluid’s kinematic viscosity is ν . The solutions to Burgers equation in the case of inviscid flow are equivalent to the method of Lighthill–Whitham. The latter method was extended to the theory of “bunching” of multiple random shock waves by Lighthill²² and Puneekar et al.²³ using Burgers equation. Additional information on nonlinear acoustics is given in Chapter 10 of this handbook.

We now turn to *aerodynamic noise*, the science of which was founded by Lighthill.¹ It is based on the

exact Navier–Stokes equations of compressible fluid flow, which apply equally to both viscous and turbulent flows. However, all mathematical theories need to be validated by experiments, and it was fortunate that such verification—that turbulence was the source of noise—was available in full from the earlier experiments on jet noise, begun in 1948, by Westley and Lilley²⁴ in England and Lassiter and Hubbard²⁵ in the United States. The theory and experiments had been motivated by the experience gained in measuring the jet noise of World War II military aircraft, the wider certain noise impact on residential areas, due to the rapid growth of civil aviation, and the introduction of jet propulsion in powering commercial aircraft. At the time of the introduction of Lighthill’s theory, a range of methods for jet noise reduction had already been invented by Lilley, Westley, and Young,²⁴ which were later fitted to all commercial jet aircraft from 1960 to 1980, before the introduction of the quieter turbofan bypass engine in 1970.

Aerodynamic noise problems differ from those of classical acoustics in that the noise is self-generated, being derived from the properties of the unsteady flow, where the intensity of the radiated sound, with its broadband frequency spectrum and its total acoustic power, are a small by-product of the kinetic energy of the unsteady flow. At low Mach numbers, the dominant wavelength of the sound generated is typically much larger than the dimensions of the flow unsteadiness. In this case we regard the sound source as compact. At high frequencies and/or higher Mach numbers the opposite occurs and the source is noncompact.

The frequency ω and wavenumber k are the parameters used in the Fourier transforms of space–time functions used in defining the wavenumber/frequency spectrum in both acoustics and turbulence analysis. Apart from the Doppler changes in frequency due to the source motion relative to a receiver, the wavenumber and frequency in the sound field generated by turbulent motion must equal the same wavenumber and frequency in the turbulence. But here we must add a word of caution since, in turbulence, the dynamic processes are nonlinear and the low wavenumber section of the turbulent energy wavenumber spectrum receives contributions from all frequencies. Thus, in a turbulent flow, where the source of noise is an eddy whose length scale is very small compared with the acoustic wavelength for the same frequency, the matching acoustic wavenumber will be found in the low wavenumber end of the turbulent energy spectrum, referred to as the acoustical range. At low Mach numbers its amplitude will be very small compared with that of wavenumbers in the so-called convective range of the turbulent energy spectrum corresponding to the same frequency in the acoustical spectrum. This may at first cause confusion, but it must be remembered that turbulent eddies of all frequencies contribute to the low wavenumber end of the energy spectrum. There is no difficulty in handling these problems in aerodynamic noise theory if we remember that ω and k always refer to the acoustic field external to the turbulent flow, with $\omega/k = c$, the speed of sound, and $\lambda = 2\pi/k$,

is the sound wavelength. The amplitude is measured by its intensity $\mathbf{I} = \mathbf{n}(c_\infty^3/\rho_\infty)\langle(\rho')^2\rangle$, where ρ' is the density perturbation due to the sound waves. The normal to the wave front is \mathbf{n} . On the other hand, the properties of the turbulence are defined by the turbulent kinetic energy,* $k_T = (\frac{1}{2})\langle(v')^2\rangle = u_0^2$, its integral length scale, ℓ_0 , and the corresponding frequency of the sound generated, ω_0 , satisfying the Strouhal number $s_T = \omega_0 \ell_0 / u_0$. In most turbulent flows $s_T \approx 1$ to 1.7. If we follow these simple rules and use relevant frequency spectra for both the acoustics and turbulence problems, the use of the wavenumber spectrum in the turbulence becomes unnecessary. This in itself is a useful reminder since the wavenumber spectrum, in the important low wavenumber acoustic region, is rarely measured, at least to the accuracy required in aeroacoustics. It is important to recognize that almost the same compressible flow wavenumber spectrum appears in the turbulence analysis for an incompressible flow, where no noise is generated. In many applications of Lighthill's theory we may put the acoustic wavenumber in the turbulence equal to zero, which is its value in an incompressible flow where the propagation speed is infinite. There are, however, many aerodynamic noise problems of interest in the field of aeroacoustics at low Mach numbers, where the equivalent acoustic sources are compact. In such cases the fluid may be treated as though it were approximately an unsteady incompressible flow.

There is no unique method available to describe the equations of aerodynamic noise generated by a turbulent flow. The beauty of Lighthill's approach, as discussed below, is that it provides a consistent method for defining the source of aerodynamic noise and its propagation external to the flow as an acoustic wave to a far-field observer. It avoids the problem of nonlinear wave propagation within the turbulent flow and ensures that the rate of dilatation fluctuations within the flow are accounted for exactly and are not subject to any approximation. Thus, it is found possible in low Mach number, and high Reynolds number, flows for many practical purposes to regard the turbulent flow field as almost incompressible. The reason for this is that both the turbulent kinetic energy and the rate of energy transfer across the turbulent energy spectrum in the compressible flow are almost the same as in an incompressible flow. It follows that, in those regions of the flow where diffusive effects are almost negligible and the thermodynamic processes are, therefore, quasi-isentropic, the density and the rate of dilatation fluctuations in the compressible flow are directly related to the fluctuations in the pressure, turbulent kinetic energy, and rate of energy transfer in the incompressible flow. They are obtained by introducing a finite speed of sound, which replaces the infinite propagation speed in the case of the incompressible flow.

*The turbulent kinetic energy is often denoted simply by k . k_T is used here to avoid confusion with the acoustic wavenumber.

The theory of aerodynamic noise then becomes simplified since the effects of compressibility, including the propagation of sound waves, only enter the problem in the uniform flow external to the unsteady almost incompressible sound sources replacing the flow. It is found that the unsteady flow is dominated by its unsteady vorticity, $\boldsymbol{\omega} = \nabla \times \mathbf{v}$, which is closely related to the angular momentum in the flow. The dimensions of the vorticity are the same as those of frequency. The noise generated is closely related to the cutting of the streamlines in the fluid flow by vortex lines, analogous to the properties of the lines of magnetic force in the theory of electricity and magnetism. A large body of experience has been built on such models, referred to as the *theory of vortex-sound* by Howe,²⁶ based on earlier work by Powell.²⁷ These methods require the distribution of the unsteady vorticity field to be known. (The success of the method is very much in the skill of the mathematician in finding a suitable model for the unsteady vortex motion.) It then follows that, based on the assumption of an inviscid fluid, that the given unsteady vorticity creates a potential flow having an unsteady flow field based on the Biot-Savart law. As shown by Howe,¹⁶ the method is exact and is easily applied to a range of unsteady flows, including those with both solid and permeable boundaries and flows involving complex geometries. Some simple acoustic problems involving turbulent flow can also be modeled approximately using the theory of vortex-sound.

The problems first considered by Lighthill were of much wider application and were applicable to turbulent flows. Turbulence is an unsteady, vortical, nonlinear, space-time random process that is self-generated. Although some compact turbulent flows at low Mach numbers can be treated by the theory of vortex-sound, the broader theory embracing the multiscale characteristics of this highly nonlinear turbulent motion, requires the treatment proposed by Lighthill, extended to higher Mach numbers by Ffowcs Williams,⁶ and by Lilley,⁷ Goldstein,¹⁰ and others to include the effects of flow-acoustic interaction.

Lighthill's theory, based on the exact compressible Navier-Stokes equations, considers the equations for the fluctuations in pressure, density, and enthalpy within an isolated domain of turbulent flow, which is being convected with the surrounding compressible and irrotational fluid, and on which it feeds to create the unsteady random vortical motion. Within the turbulent fluid of limited extent, the equations for the unsteady pressure, and the other flow variables, are all nonlinear. However, Lighthill was able to show that beyond a certain distance from the flow, of the order of an acoustic wavelength, the sound waves generated by the turbulent motion satisfy the standard linear wave equation and are thus propagating outward at the speed of sound in the uniform medium external to the flow. In Lighthill's original work the uniform medium external to the flow was at rest.

Lighthill realized that much of the unsteadiness within the flow and close to its free boundaries, related to nonlinear turbulent fluid dynamics, with

the influence of the turbulence decaying rapidly with distance from the flow. Moreover, an extremely small fraction of the compressible flow kinetic energy escapes from the flow as radiated sound. In the near field of the source of noise, the surging to and fro of the full flow energy produces almost no net transport of energy along the sound ray from the source to far-field observer. Lighthill devised a method by which this small fraction of the kinetic energy of the nonlinear turbulent motion, escaping in the form of radiated sound, could be calculated without having first to find the full characteristics of the nonlinear wave propagation within the flow. Lighthill was concerned that the resulting theory should not only include the characteristics of the turbulent flow but also the corresponding sound field created within the flow and the interaction of the turbulence on that sound field as it propagated through the flow field before escaping into the external medium. But all these effects contributing to the amplitude of the noise sources within the flow were, of course, unknown a priori. Lighthill thus assumed that, for most practical purposes, the flow could be regarded as devoid of all sound effects, so that at all positions within the flow, sound waves and their resulting sound rays generated by the flow unsteadiness, would travel along straight lines between each source and a stationary observer in the far acoustic field in the medium at rest. Such an observer would receive packets of sound waves in phase from turbulence correlated zones, as well as packets from uncorrelated regions, where the latter would make no contribution to the overall sound intensity. Thus Lighthill reduced the complex nonlinear turbulent motion and its accompanying noise radiation, into an equivalent linearized acoustical problem, or *acoustical analogy*, in which the complete flow field, together with its uniform external medium at rest, was replaced by an equivalent distribution of moving acoustic sources, where the sources may move but not the fluid. The properties of this equivalent distribution of moving acoustic sources has to be determined a priori from calculations based on simulations to the full Navier–Stokes equations or from experiment.

Therefore, we find that *Lighthill's inhomogeneous wave equation* includes a left-hand side, the propagation part, which is the homogeneous wave equation for sound waves traveling in a uniform medium at rest, and a right-hand side, the generation part, which represents the distribution of *equivalent acoustic sources* within what was the flow domain. The latter domain involves that part of the nonlinear turbulent motion that generates the sound field. As written, Lighthill's equation is exact and is as accurate as the Navier–Stokes equations on which it is based. In its applications, its right-hand side involves the best available database obtained from theory or experiment. Ideally, this is a time-accurate measurement or calculation of the properties of the given compressible turbulent flow, satisfying appropriate boundary and initial conditions. In general, this flow would be measured or calculated on the assumption that the sound field present in the flow has a negligible back reaction on the turbulent flow.

However, Ffowcs Williams and Hawkings⁵ found a solution to Lighthill's equation, which can be used to find the far-field sound intensity, directivity, and spectrum, once the time-dependent properties of the turbulent flow, together with its acoustic field, are known on any arbitrary moving permeable surface within the flow, called the Ffowcs Williams–Hawkings acoustical data surface, and embracing the dominant noise sources within the flow. Volume sources external to the Ffowcs Williams–Hawkings surface have to be calculated separately. It should be noted that in all computer simulations, the required information on the data surface is rarely available. The exception is direct numerical simulation (DNS); see Section 8. The data are normally unresolved at high frequencies that are well within the range of interest in aeronautical applications.

Earlier in this section, the theory of nonlinear acoustics was introduced along with the Lighthill–Whitham theory, with its application to derive the pattern of shock waves around a body, such as an aircraft, traveling at supersonic speeds. Shock waves are finite-amplitude sound waves. Their speed of propagation is a function of their strength, or pressure rise, and therefore they travel at speeds greater than the speed of sound. Shock waves are absent from aircraft flying at subsonic speeds. The acoustical disturbances generated by the passage of subsonic aircraft travel at the speed of sound, and the sound waves suffer attenuation with distance from the aircraft due to spherical spreading. The noise created by subsonic aircraft is discussed in Section 9.4. An aircraft flying at supersonic speeds at constant speed and height creates a pattern of oblique shock waves surrounding the aircraft, which move attached to the aircraft while propagating normal to themselves at the speed of sound. These shock waves propagate toward the ground and are heard as a double boom, called the sonic boom, arising from the shock waves created from the aircraft's nose and tail. The pressure signature at ground level forms an *N*-wave comprising the overpressure of the bow shock wave followed by an expansion and then the pressure rise due to the tail wave. The strength of the sonic boom at ground level for an aircraft the size of the Concorde flying straight and level at $M = 2$ is about 96 N/m^2 or 2 lbf/ft^2 . An aircraft in accelerated flight flying at supersonic speeds, such as in climbing flight from takeoff to the cruising altitude, develops a superboom, or focused boom. The shock waves created from the time the aircraft first reached sonic speed pile up, since the aircraft is flying faster than the waves created earlier along its flight trajectory. The superboom has a strength at ground level many times that of the boom from the aircraft flying at a constant cruise Mach number. The flight of supersonic aircraft over land over towns and cities is presently banned to avoid minor damage to buildings and startle to people and animals. The theory of the sonic boom is given by Whitham.²¹ Further references are given in Schwartz.²⁸

4 DERIVATION OF Lighthill's EQUATION FOR AERODYNAMIC NOISE

The exact equations governing the flow of a compressible fluid are the nonlinear Navier–Stokes equations. These equations for the conservation of mass, momentum, and heat energy are, respectively,

$$\begin{aligned} \frac{D\rho}{Dt} + \rho \nabla \cdot \mathbf{v} &= 0 & \rho \frac{D\mathbf{v}}{Dt} + \nabla p &= \nabla \cdot \boldsymbol{\tau} \\ \rho \frac{Dh}{Dt} - \frac{Dp}{Dt} &= \nabla \cdot \mathbf{q} + \boldsymbol{\tau} : \nabla \mathbf{v} \end{aligned} \quad (10)$$

where the conservation of entropy is represented by $\rho T Ds/Dt \equiv \rho Dh/Dt - Dp/Dt$. The heat flux vector is \mathbf{q} , the viscous stress tensor (dyadic*) is $\boldsymbol{\tau}$, $\gamma = C_p/C_v$ is the ratio of the specific heats, and s is the specific entropy. The nonlinear operator following the motion is $D/Dt \equiv \partial/\partial t + \mathbf{v} \cdot \nabla$. We see that, with the diffusive terms included, the thermodynamic processes are nonisentropic. The equation of state for a perfect gas is $p = (\gamma - 1)\rho h/\gamma$, and the enthalpy, $h = C_p T$, where T is the absolute temperature. These are six equations for the six unknowns ρ , p , h , and \mathbf{v} .

To clarify the generation of aerodynamic noise by turbulence, defined as random unsteady vortical motion, we consider the special case of a finite cloud of turbulence moving with an otherwise uniform flow of velocity, \mathbf{V}_0 . In the uniform mean flow all flow quantities are described by the subscript zero. The fluctuations of all quantities are denoted by primes. Internal to the flow, primed quantities will be predominately turbulent fluctuations since the fluctuations due to sound waves are relatively very small. External to the turbulent flow, the flow is irrotational and includes not only the unsteady sound field but also the entrainment induced by the turbulent flow and on which the turbulent flow feeds. The characteristics of the entrainment are an essential part of the characteristics of the turbulent flow, but its contribution to the radiated noise is known to be small and will be neglected in our analysis. We introduce the linear operator following the uniform mean motion, $D_0/Dt \equiv \partial/\partial t + \mathbf{V}_0 \cdot \nabla$, which is equivalent to a coordinate frame moving with the mean flow velocity \mathbf{V}_0 . In many turbulent flows the density fluctuations, internal to the turbulent flow, do not greatly influence the structure of the turbulent flow and, except in the case of high-temperature and/or high-velocity

flows, are small in comparison with the mean flow density. Here we shall neglect, for convenience only, the product $\rho'\mathbf{v}'$ and $\rho'h'$ compared with $\rho_0\mathbf{v}'$ and ρ_0h' , respectively. Thus, our simplified conservation equations for mass, momentum, heat energy, and turbulent kinetic energy for a turbulent flow, noting that the derivatives of all quantities appear as their fluctuations only become, respectively[†]

$$\frac{D_0\rho'}{Dt} + \nabla \cdot \rho_0\mathbf{v}' = 0 \quad (11)$$

$$\frac{D_0}{Dt}(\rho_0\mathbf{v}') + \nabla \cdot (\rho_0\mathbf{v}'\mathbf{v}' - \boldsymbol{\tau}') + \nabla p' = 0 \quad (12)$$

$$\begin{aligned} \frac{D_0\rho_0h'}{Dt} + \nabla \cdot \rho_0\mathbf{v}'h' - \frac{D_0p'}{Dt} - \mathbf{v}' \cdot \nabla p' \\ = \nabla \cdot \mathbf{q}' + \boldsymbol{\tau}' : \nabla \mathbf{v}' \end{aligned} \quad (13)$$

$$\begin{aligned} \frac{D_0\rho_0(v')^2/2}{Dt} + \frac{\nabla \cdot \rho_0\mathbf{v}'(v')^2}{2} + \mathbf{v}' \cdot \nabla p' \\ = \nabla \cdot (\boldsymbol{\tau}' \cdot \mathbf{v}') - \boldsymbol{\tau}' : \nabla \mathbf{v}' \end{aligned} \quad (14)$$

where at high Reynolds numbers, except in the region close to solid boundaries, the viscous diffusion term, $\nabla \cdot (\boldsymbol{\tau}' \cdot \mathbf{v}')$, can be neglected. However, the viscous dissipation function, $\boldsymbol{\tau}' : \nabla \mathbf{v}' = \rho_0 \epsilon'_{\text{diss}}$ is always finite and positive in a turbulent flow. The heat flux, $\nabla \cdot \mathbf{q}'$, also contains a diffusion part, which is negligible at high Reynolds numbers except close to solid boundaries, plus a dissipation part, which must be added to $\boldsymbol{\tau}' : \nabla \mathbf{v}'$ in the heat energy equation. In the section below describing the characteristics of turbulent motion, we will discuss how the dissipation function equals the rate of energy exchange across the turbulent energy spectrum. Turbulent flow processes are never completely isentropic, but since energy dissipation only occurs in the smallest scales of turbulence, the rate of energy transfer is almost

*We have chosen to use vector notation throughout this chapter for consistency. In order to accommodate tensor forms, it is necessary to introduce dyadics.²⁹ Thus, the shear stress tensor is represented by the dyadic $\boldsymbol{\tau}$ and has nine components. The operation $\nabla \cdot \boldsymbol{\tau}$ is equivalent to $\partial \tau_{ij}/\partial x_j$ and gives a vector. The colon denotes a scalar or inner product of two dyadics and gives a scalar. For example, $\boldsymbol{\tau} : \nabla \mathbf{v}$ is equivalent to $\tau_{ij}\partial v_i/\partial x_j$. The dyadic or tensor product of two vectors gives a tensor. For example, $\mathbf{v}\mathbf{v}$ (sometimes $\mathbf{v} \otimes \mathbf{v}$) is equivalent to $u_i u_j$. The identity dyadic, equivalent to the Kronecker delta, is denoted by $\boldsymbol{\mathcal{I}}$.

[†]In this set of equations there is no flow-acoustics interaction since the mean velocity is a constant everywhere and no gradients exist. In a nonuniform flow, gradients exist and additional terms arise involving products of mean velocity gradients and linear perturbations. These additional terms, which have zero mean, are not only responsible for flow-acoustics interaction, but play an important role in the properties of the turbulence structure, and the turbulence characteristics. They do not control the generation of aerodynamic noise. Lighthill, in his original work, assumed their bulk presence could be regarded as an effective source of sound, but this interpretation was incorrect since their contribution to the generated sound must be zero. *Flow-acoustic interaction could be considered after the solution to Lighthill's equation has been performed for the given distribution of noise sources.* The alternative is to include the mean velocity and temperature gradients in the turbulent flow as modifications to the propagation in Lighthill's equation, but not the generation terms. The latter proposal is the extension to Lighthill's theory introduced by Lilley.⁷

constant from the largest to the smallest eddies. From the time derivative of the equation of continuity and the divergence of the equation of motion, we find, respectively, two equations for the time variation of the rate of dilatation:

$$\begin{aligned} \frac{D_0}{Dt}(\rho_0\theta') &= -\frac{D_0^2\rho'}{Dt^2} - \frac{D_0}{Dt}(\rho_0\theta') \\ &= -\nabla \cdot \nabla \cdot (\rho_0\mathbf{v}'\mathbf{v}' - \boldsymbol{\tau}') - \nabla^2 p' \quad (15) \end{aligned}$$

These equations for the fluctuations in θ' show that inside the turbulent flow the fluctuations in the rate of dilatation are almost negligible compared with the dominant terms on the right-hand side. Nevertheless if they were zero there would be no density fluctuations and therefore no noise would be radiated from the flow.

This was a most significant feature of Lighthill's theory of aerodynamic noise, in that although θ' is an extremely small quantity, and is almost impossible to measure, it must never be put equal to zero in a compressible flow. Its value $\theta' = O(\varepsilon'_T/c_0^2)$, where† $\varepsilon'_T \approx \varepsilon'_{diss}$, and shows the relative smallness of the rate of loss of energy relating to noise radiation from the turbulent kinetic energy and the rate of energy transfer in the nonlinear turbulent energy cascade.*

Hence, on eliminating $D_0/Dt(\rho_0\theta')$ between the two equations, we find Lighthill's Galilean invariant, convected wave equation for the fluctuating pressure:

$$\begin{aligned} \left(\frac{1}{c_\infty^2} \frac{D_0^2}{Dt^2} - \nabla^2\right) p' &= \nabla \cdot \nabla \cdot (\rho_0\mathbf{v}'\mathbf{v}' - \boldsymbol{\tau}') \\ &+ \frac{1}{c_\infty^2} \frac{D_0^2}{Dt^2} (p' - c_\infty^2\rho') \quad (16) \end{aligned}$$

and for the fluctuating density, as was shown earlier by both Lilley⁷ and Dowling et al.,³⁰

$$\left(\frac{D_0^2}{Dt^2} - c_\infty^2 \nabla^2\right) \rho' = \nabla \cdot \nabla \cdot \boldsymbol{\mathcal{T}} \quad (17)$$

where Lighthill's stress tensor is $\boldsymbol{\mathcal{T}} = \rho_0\mathbf{v}'\mathbf{v}' - \boldsymbol{\tau}' + \mathcal{I}(p' - c_\infty^2\rho')$. We note the different right-hand sides to these wave equations for p' and ρ' . However, their solutions lead to the same value for the acoustic intensity in the radiation field.

The turbulent energy conservation equation is important in all work involving turbulent flow and

aeroacoustics. If we assume $p' = c_0^2\rho'$, as in linear acoustics above, we find

$$\begin{aligned} \frac{D_0}{Dt} \left[\frac{\rho_0(v')^2}{2} + \frac{(p')^2}{2\rho_0 c_0^2} \right] + \nabla \cdot \mathbf{v}' \left[p' + \frac{\rho_0(v')^2}{2} \right] \\ = -\rho_0 \varepsilon'_{diss} \quad (18) \end{aligned}$$

which is the turbulent kinetic energy conservation equation. This may be written in a similar form to that of the corresponding equation in linear acoustics given above, namely

$$\frac{D_0 w}{Dt} + \nabla \cdot \mathbf{I} = -\rho_0 \varepsilon'_{diss} \quad (19)$$

where in the turbulent flow $w = [\rho_0(v')^2/2 + (p')^2/(2\rho_0 c_0^2)]$ and $\mathbf{I} = \mathbf{v}'[p' + \rho_0(v')^2/2]$. Within the turbulent flow the velocity and pressure fluctuations are dominated by the turbulent fluctuations, but external to the turbulent cloud $\rho_0 \varepsilon'_{diss}$ is effectively zero and p' and \mathbf{v}' are then just the acoustical fluctuations arising from the propagating sound waves generated by the turbulence in the moving cloud. In the acoustic field external to the flow, $\rho_0(v')^2/2 \ll |p'|$. Within the turbulent flow the fluctuating pressure, $p' = O[\rho_0(v')^2]$. In Lighthill's convected wave equation for aerodynamic noise, when the flow variable is p' , the source includes $(1/c_\infty^2)(D_0^2/Dt^2)(p' - c_\infty^2\rho')$ and was called by Lighthill the nonisentropic term. For flows at near ambient temperature this term can be neglected. However, we can show, following Lilley,⁷ by neglecting the diffusion terms in high Reynolds number flows in the equation for the conservation of stagnation enthalpy, that

$$\begin{aligned} \frac{1}{c_\infty^2} \frac{D_0}{Dt} (p' - c_\infty^2\rho') &= -\frac{\gamma-1}{2c_\infty^2} \frac{D_0}{Dt} \rho_0(v')^2 \\ &- \frac{\gamma-1}{2c_\infty^2} \nabla \cdot \rho_0\mathbf{v}'(v')^2 - \nabla \cdot \rho_0\mathbf{v}' \left(\frac{h'}{h_\infty} \right) \quad (20) \end{aligned}$$

noting $c_\infty^2 = (\gamma-1)h_\infty$. All the equivalent acoustic source terms in Lighthill's equation are nonlinear in the fluctuations of the turbulence velocity and enthalpy or temperature. In most turbulent flows at high Reynolds number the fluctuations in the viscous stress tensor, $\boldsymbol{\tau}'$, can be neglected compared with the fluctuations in the Reynolds stress tensor $\rho_0\mathbf{v}'\mathbf{v}'$, but the fluctuations in the dissipation function, $\rho_0 \varepsilon'_{diss}$ are always finite. In an incompressible flow, generating zero noise, $\nabla^2 p' = -\nabla \cdot \nabla \cdot (\rho_0\mathbf{v}'\mathbf{v}')$, and in a compressible flow this same relation almost holds, where the difference is entirely due to the removal of the rate of dilatation constraint, $\nabla \cdot \mathbf{v}' = 0$. It was shown by Lighthill that the effective strength of the equivalent noise sources could be obtained by writing $\nabla \approx -(1/c_\infty)D_0/Dt$, multiplied by the direction cosine of the position of

*Since $c_0^{-2}D_0 p'/Dt = D_0 \rho'/Dt = -\rho_0\theta'$, we find, $D_0 p'/Dt = -\rho_0 c_0^2\theta' = O(\rho_0\omega_0 u_0^2)$, which confirms the value given.

† ε'_T is the rate of energy transfer from the large to the small eddies, which almost equals the rate of energy dissipation, ε'_{diss} in both compressible and incompressible flow. $\varepsilon'_T \approx O(u_0^3/\ell_0) \approx O(u_0^2\omega_0)$.

the observer relative to that of the source. Thus for the far-field noise

$$\left(\frac{D_0^2}{Dt^2} - c_\infty^2 \nabla^2 \right) \rho' \sim \frac{1}{c_\infty^2} \frac{D_0^2 \mathcal{T}_{xx}}{Dt^2} \quad (21)$$

where

$$\begin{aligned} \mathcal{T}_{xx} = c_\infty^2 \left[\frac{\rho_0(v'_x)^2}{c_\infty^2} - \frac{\gamma-1}{2} \frac{\rho_0(v')^2}{c_\infty^2} \right. \\ \left. + \frac{\gamma-1}{2} \frac{\rho_0 v'_x(v')^2}{c_\infty^3} + \rho_0 \frac{v'_x}{c_\infty} \frac{h'}{h_\infty} \right] \quad (22) \end{aligned}$$

and the subscript x refers to components resolved in the direction between source and observer. The first term was derived from a double divergence and is an acoustic quadrupole source. It equals the fluctuations in the normal components of the turbulence Reynolds stress in the direction of the observer, since in turbulent flows of ambient temperature $\mathcal{T}_{xx} = \rho_0(v'_x)^2$. The second is a monopole having the same strength as a quadrupole. The third and fourth terms were derived from a single divergence and are therefore dipole. The two dominant sources are the first and the last. The first term leads to a far-field acoustic intensity proportional to the eighth power of the turbulent velocity, while the last term is proportional to the sixth power of the turbulent velocity. In an unheated flow the last term is absent, but in a heated flow at low Mach numbers it exceeds the first in magnitude.

The special case, originally considered by Lighthill, was for a cloud of turbulence moving at a constant convection speed through an external medium at rest. This case can be recovered by putting $\mathbf{V}_0 = 0$. The solution to Lighthill's unique wave equation in the coordinates of the observer in the far field at rest is given by the convolution of the source terms with the free space Green's function. If the acoustic wavelength is assumed to be much greater than the characteristic dimension of the source region, a compact source distribution, then the far-field density fluctuation is given approximately by

$$\rho'(\mathbf{x}, t) \sim \frac{1}{4\pi c_\infty^4 R} \int_{\mathcal{V}} \frac{\partial^2 \mathcal{T}_{xx}}{\partial \tau^2} \left(\mathbf{y}, t - \frac{R}{c_\infty} \right) d^3 \mathbf{y} \quad (23)$$

where $R = |\mathbf{x}| \simeq |\mathbf{x} - \mathbf{y}|$, and \mathcal{V} denotes the flow volume containing the equivalent noise sources. The retarded time, $\tau = t - R/c_\infty$, is equal to the source, or emission time. The observer time is t .

Here the distribution of the equivalent sound sources is given by $\mathcal{T}_{xx} = \mathcal{T}_{ij} x_i x_j / x^2$, which is also Lighthill's fluctuating normal stress in the direction of the observer at \mathbf{x} , and the variation with observer location $\partial/\partial x_i$ has been replaced by $-(1/c_\infty)(x_i/x) \partial/\partial t$. Equation (23) shows that the far-field density is given by the integral over the source volume of the second

time derivative of the Lighthill stress tensor evaluated at the emission, or retarded time, $\tau = (t - R/c_\infty)$.

Lighthill considered the emission of sound from each moving source as it crossed a fixed point, \mathbf{y} , in the coordinates at rest at the retarded time, $\tau = t - |\mathbf{x} - \mathbf{y}|/c_\infty$ where the observer's coordinates are (\mathbf{x}, t) . If the velocity of each source relative to the observer at rest is V_c , then the frequency of the sound received by the observer, $\omega = \omega_0/C_\theta$, where ω_0 is the frequency of the source at emission in the moving frame, and

$$C_\theta = \sqrt{(1 - M_c \cos \theta)^2 + (\omega_0 \ell_1 / c_\infty)^2 \times (\cos^2 \theta + (\ell_\perp / \ell_1)^2 \sin^2 \theta)} \quad (24)$$

is the generalized Doppler factor, which is finite even when $M_c \cos \theta = 1$. The different integral turbulence length scales ℓ_1 and ℓ_\perp , which are in the directions of the mean motion and transverse, respectively, are discussed later. $M_c = V_c/c_\infty$ is the "acoustical" convection Mach number. The equivalent acoustic source in the moving frame has the same strength per unit volume, namely \mathcal{T} , as discussed above involving the non-linear turbulence fluctuations alone. Lighthill's model is always a "good" first approximation even though it neglects flow-acoustical interaction, caused by refraction and diffraction effects on sound emitted by the sources and then traveling through a nonuniform mean flow. Although it is permitted to use different convection speeds according to the local distribution of mean velocity in a free shear or boundary layer flow, it is normally found sufficient to use an averaged convection speed for any cross section of the moving "cloud" of turbulence. The convection theory of aerodynamic noise is referred to as the Lighthill-Ffowcs Williams convection theory and is applicable to all Mach numbers. The success of this theory is seen by the results shown in Fig. 1 obtained from experiment over an extended range of subsonic and supersonic jet exit Mach numbers from jet aircraft and rockets. The solid line in this figure is simply an empirical curve connecting the theoretical asymptotic limits of jet noise proportionality of V_j^8 at moderate to high subsonic jet exit Mach numbers, with V_j^3 at high supersonic speeds. The full extent of confirmation between experiment and theory cannot be obtained by comparison with one single curve since the theory is dependent on both the values of jet exit Mach number and jet exit temperature and applies to shock-free jets only. A more relevant comparison is shown in Figs. 3 and 4 for jets of various temperature ratios at subsonic to low supersonic speeds, where the "acoustical" convection Mach number, $M_c = V_c/c_\infty$, is less than unity, and the jets are therefore free of shocks. The theoretical curve in these figures is that calculated from the Lighthill-Ffowcs Williams formula and is shown also in Fig. 2 for the single jet temperature ratio of unity. It is based on the generalized Doppler factor, C_θ , given by Eq. (24) for a constant turbulence Strouhal number, s_T , a characteristic turbulence velocity, u_0 , proportional to the jet

constant nozzle exit area is given by

$$P_{ac} = \text{constant} \times M_j^8 \left(\int_0^\pi C_\theta^{-5/2} \sin \theta d\theta \right) \quad (26)$$

exit velocity V_j , and a mean convection velocity V_c proportional to V_j , such that

$$C_\theta = \sqrt{(1 - M_c \cos \theta)^2 + \alpha^2 M_c^2} \quad (25)$$

exists for all values of M_j , for shock-free conditions in the jet. In Fig. 1.2 α has the value of $\frac{1}{2}$ and $V_c/V_j = 0.62$. The total acoustic power for such an ideal jet operating at ambient temperature and for a

Equation (26) shows that when $M_j \ll 1$, the total acoustic power varies as M_j^8 . In the limit of $M_j \gg 1$, the total acoustic power varies as M_j^3 , but this limit is not reached until $M_j = 3$.

The constant is a function of the jet exit temperature ratio. The theoretical curve is for one temperature ratio only. Therefore, it is not possible to compare this theoretical result with experimental results for a range of temperature ratios in one figure with a single curve. However, the spread of results with temperature ratio, except at low jet Mach numbers, is far less important than with the variation in jet velocity. Thus, Fig. 2 demonstrates the change in velocity dependency of the total jet acoustic power that occurs as the jet exit velocity changes from subsonic to supersonic speeds, with respect to the ambient speed of sound. In particular, the velocity power law changes from V_j^8 at low subsonic Mach numbers to V_j^3 at high supersonic Mach numbers. But a remarkable feature of this comparison between the convective amplification theory and experiment, is that it clearly shows that in the experiments the departure from the V_j^8 law at high subsonic Mach numbers is not present. The explanation is simply that although the convective amplification theory is correct in respect of sound amplitude, the directivity of the propagated sound is modified as a result of flow–acoustical interaction. The latter is clearly demonstrated in the downstream

direction of a jet by the almost complete zone of silence, especially at high frequencies, present in an angular range around the jet centerline. Thus, we find for much of the subsonic range, for jets at ambient temperatures or for heated jets, except at low jet Mach numbers, the noise intensity varies as V_j^8 , and similarly for much of the supersonic and hypersonic regime, the variation is with V_j^3 . This is also shown in Figs. 3 and 4.

When the flow is supersonic and shock waves appear inside the turbulent flow, models need to be introduced to include the effects of shock and expansion waves on the turbulent shear layer development. The theory is modified when turbulence is in the presence of solid walls, and when the turbulence is scattered as it crosses the trailing edge of a wing in flowing to form the wing wake. All these separate cases are considered below, and in each case the Lighthill stress

(From Lilley.³⁹)

tensor, \mathcal{T} , provides the major characteristics of the equivalent source of noise per unit volume, but whose value must be obtained from experiment or from models based on solutions to the Navier–Stokes equations.

The case of turbulent flows, where the mean flow is nonuniform, presents a special case. In Lighthill's original work the turbulent flow Mach numbers were small and sound sources were compact with the acoustic wavelength exceeding the dimensions of the flow. Lighthill argued that the flow fluctuations should include not only the turbulent flow fluctuations but also the fluctuations arising from the sound field created by the turbulence in the flow. Nevertheless, it had to be assumed when considering the propagation of the sound that no sound existed inside the flow. However, it also had to be assumed that the sound, generated at a source within the flow, traveled at the speed of sound along the ray following the straight line joining the emission point y with the observer at x , in the external ambient medium at rest. In this model there was no flow-acoustical interaction.

Early measurements showed flow-acoustics interaction was important with respect to the directivity of the far-field sound intensity. The investigations of pressure fluctuations by Lilley³² within a turbulent flow suggested that the wavenumber spectrum was dominated by two dominant processes, one was called the mean shear interaction and the other was called the turbulence–turbulence interaction. The former process dominated the lower frequencies, including the peak in the spectrum, and most of the inertial range. The latter dominated the higher frequencies and wavenumbers. The resultant models for the mean square of the turbulent pressure fluctuations fitted the available experimental data, confirming that the linear products in the complete Reynolds stress tensor were responsible for the dominant characteristics of turbulent mixing. But this presented a conflict since, if the same models were used in Lighthill's stress tensor, it implied that it should include linear terms involving products of mean and turbulent velocity components. But, as derived above, we found that Lighthill's stress tensor must only include products of turbulent velocity fluctuations, and measurements had confirmed that the amplitude of the radiated sound depended on the product of the turbulent velocity components in the fluctuations of the Reynolds stress tensor, which dominate Lighthill's stress tensor.

Lilley⁷ and Goldstein¹⁰ showed that all linear fluctuations in the conservation equations were responsible for flow-acoustic interactions, which is part of propagation, and only nonlinear fluctuations were responsible for noise generation. It was demonstrated that the linear perturbation terms in the Euler equations were responsible for flow-acoustic interaction and modified the propagation section of Lighthill's wave equation, which became an exact generalized third-order linear wave equation for the simple case of a parallel mean shear turbulent flow. Its homogeneous form is known as the Pridmore-Brown equation.³³ The generation part of the equation was also modified and

included a modified form of Lighthill's source function plus an additional contribution from a product term, involving the local mean shear times components of the nonlinear Lighthill stress tensor. Other authors have tried to replace Lilley's third-order inhomogeneous equation with approximate second-order equations, claiming these can include the effects of both generation and flow-acoustical interaction. However, all these attempts have failed as can easily be seen from inspection of the complete Euler equations, from which Lilley's equation was derived.* These equations, written as linearized Euler equations with the nonlinear source terms similar to the components of Lighthill's stress tensor, can be solved using the adjoint method introduced by Tam and Auriault.⁸ The solution to Lilley's equations involves Green's functions expressed in Airy functions and is similar to the solution of equations found by Brekhovskikh³⁴ in wave propagation in multilayered media. The theory of acoustical-flow interaction shows the importance

*Howe²⁶ derived an exact second-order nonlinear wave equation for aerodynamic noise in the flow variable $B = h + v^2/2$:

$$\frac{D}{Dt} \left(\frac{1}{c^2} \frac{DB}{Dt} \right) - \nabla^2 B + \frac{\nabla h \cdot \nabla B}{c^2} = -\nabla \cdot (\mathbf{v} \times \boldsymbol{\omega}) + \frac{\mathbf{v} \times \boldsymbol{\omega}}{c^2} \cdot \frac{D\mathbf{v}}{Dt} \quad (27)$$

which only has simple analytic solutions when both the nonlinear operators and source terms are linearized. Most of the terms discarded in the linearization in applications to turbulent flows, are turbulent fluctuating quantities, which should rightly be included in the noise generating terms. *The resultant approximate equation is, therefore, not applicable for turbulent flows and problems involving flow-acoustic interaction.* Its merit is in showing that a "good" approximation to Lighthill's stress tensor is $\nabla \cdot (\mathbf{v} \times \boldsymbol{\omega})$, which is known to be important in the theory of vortex-sound and in the structure of turbulent flows. The claim that the convected wave equation based on the stagnation enthalpy, B , provides the true source of aerodynamic noise is, we believe, an overstatement because unless all convective terms are removed from the source terms and all turbulent fluctuations are removed from the propagation it is impossible to judge the true nonlinear qualities of the source. This has been achieved with our presentation of Lighthill's theory and the generalized theory of Lilley presented below. Indeed the starting point of the latter work was the second-order equation

$$\left(\frac{D^2}{Dt^2} - \nabla(c^2 \nabla) \right) \chi = \nabla \mathbf{v} : \nabla \mathbf{v} \quad (28)$$

where $\chi = \ln \rho$, which is an even simpler nonlinear equation than that derived by Howe. But the expanded version of this equation reduces to a third-order generalized inhomogeneous wave equation, where its left-hand side involves only a linear operator. The expanded form of Howe's equation required in turbulent shear flows also reduces to a third-order equation.

of sound refraction within the flow especially in the higher frequencies of sound generation within the turbulence. In the case of jet noise, high-frequency sound waves propagating in directions close to the jet axis are refracted by the flow and form a zone of silence close to the jet boundary. Figure 3 shows how sound refraction almost cancels the convective amplification effects of the Lighthill-Ffowcs Williams theory in the case of the total acoustic power from "cold," or ambient, jet flows at high subsonic and low supersonic Mach numbers. Figure 4 shows similar results for the total acoustic power of hot jets showing that, at high Reynolds numbers, hot jets at low Mach numbers radiate proportional to M_j^6 , while at Mach numbers greater than about $M_j = 0.7$ they radiate proportional to M_j^8 . Reference should also be made to Mani.³⁵ For recent experiments on heated jet noise, reference should also be made to Viswanathan.³⁶

Before using these results to obtain scaling laws for the noise radiated by jets, some discussion of the characteristics of the structure of turbulent shear flows is given.

5 STRUCTURE OF TURBULENT SHEAR FLOWS

Before considering the special properties of the turbulent structure of a turbulent jet at high Reynolds numbers, we will first discuss some general properties of turbulent shear flows.

The experimental work of Townsend⁴² and others over the past 50 years have provided details of the mean structure of turbulent shear flows and have enabled models to be developed for the mean velocity and pressure distributions in both incompressible and compressible flows. However, in aerodynamic noise calculations we require not only the details of the averaged structure of the turbulent shear flow but also the time-accurate properties of the flow, involving the fluctuations in all the physical variables. Such details are difficult to obtain experimentally, both in respect of the instrumentation required, and that the time for measurements having the required accuracy is normally prohibitive. Even with today's large supercomputers, and with the use of computer clusters, it is still impossible to simulate turbulent flows at high Reynolds number with meaningful data to predict the full-scale noise characteristics from turbulent jets and boundary layers. Direct numerical simulation (DNS) has produced results at low Reynolds numbers, but such calculations are very expensive and time consuming. Moreover, important changes in the structure of jets and boundary layers, including attached and separated flows, occurs with increases in Reynolds number, so that noise prediction is heavily reliant on accumulated full-scale experimental data, including noise measurements involving phased arrays, and particle image velocimetry (PIV) and laser Doppler velocimetry (LDV) within the flow. However, the use of approximate results for the determination of the noise generation from turbulent shear flows, based largely on a knowledge of the averaged turbulent

structure, has produced results that have helped in the formulation of approximate methods, which can then be calibrated against the full-scale flow and far-field noise databases.

It is from flow visualizations, using smoke, schlieren, and shadowgraph, that a qualitative understanding is obtained of the global features of the turbulent flow field, as well as many of its time-dependent features. Moreover, such results can usually be obtained quickly and always help in planning more quantitative follow-on experiments. At sufficiently high Reynolds numbers, the mixing between two or more adjacent fluids flowing at different speeds, and/or temperatures, generates a shear layer of finite thickness, where the perturbation fluctuations are unstable and the mixing, which is initially laminar, eventually passes through a transition zone and becomes turbulent. Turbulence is described as a random eddying motion in space and time and possesses the property vorticity, $\omega = \nabla \times \mathbf{v}$, relating to the development of spatial velocity gradients in the flow, typical of the vortices seen in flow visualizations. Outside any turbulent flow the motion is irrotational. All turbulent flow feeds on the external irrotational motion and the vorticity in the turbulent motion cannot be sustained without entrainment of the irrotational ambient fluid. The entrainment into a turbulent flow may be at a lower velocity than the turbulent flow, but its rate of mass flow, in general, far exceeds that of the primary turbulent flow. Important changes such as stretching and distortion occur to the flow as it crosses the boundary, known as the superlayer, between the irrotational and turbulent motion. The generation of sound in a compressible turbulent flow relates to its density fluctuations, corresponding to its pressure fluctuations, which are almost adiabatic, as well as local changes in volume, relating to the rate of dilatation in the turbulent fluid, where the latter are zero in an incompressible flow, where sound waves do not exist.

Townsend⁴² showed that although turbulence contains a very broad range of length scales and frequencies, its structure can be represented approximately in terms of three scales. These include a large-scale structure, the order of the local width of the shear layer, and a smaller scale structure containing the bulk of the kinetic energy in the turbulence. The third scale had been suggested earlier by Kolmogorov⁴³ as the scale of the very small dissipating eddies, whereby the energy of the turbulence is lost in transformation into heat. Kolmogorov proposed that, whereas the large-scale turbulent motion was dependent on the initial and boundary conditions for the flow and therefore was flow dependent and anisotropic, the small-scale motion was so far removed from the large-scale and energy-containing scales, that its dynamics were the same for all flows and should be locally isotropic. The hypothesis was introduced that the small-scale structure of turbulence was in almost universal equilibrium. An energy cascade was visualized, whereby energy was exchanged nonlinearly between the large-scale eddies and those containing most of the energy and followed by further nonlinear energy exchange from one scale

to the next smaller, finally down to the Kolmogorov dissipation scale. Remarkably, it has been shown that the rate of energy transferred in the energy cascade is almost lossless, even though the detailed physical processes involved are not fully understood. Work by Gaster et al.⁴⁴ and Morris et al.⁴⁵ has shown that the large-scale motion in shear flow turbulence is structured on the instability of the disturbed motion and can be calculated on the basis of the eigenmodes of linear instability theory. The full motion is nonlinear. (That the large-scale structure of shear flow turbulence could be calculated from the eigenmodes of linear instability theory was a surprising deduction, but a highly important one in the theory of turbulence. It is consistent with the notion that the structure of turbulent flows is dominated by solutions to the nonlinear inhomogeneous unsteady diffusion equation, which involve the eigenmodes of the linear homogeneous equation. The uncovering of the complexity of this nonlinear theory of turbulent mixing and evaluation of its time-accurate properties is the goal of all turbulent flow research.)

In a jet at high Reynolds number, the turbulent mixing region immediately downstream of the nozzle exit grows linearly with distance, with its origin close to the nozzle exit. The conical mixing region closes on the nozzle centerline approximately five jet diameters from the nozzle exit for a circular nozzle. This region is known as the potential core of the jet since the velocity along the nozzle centerline remains constant and equal to the jet exit velocity. Beyond the potential core, for a circular jet, the centerline velocity varies inversely with axial distance and the jet expands linearly. The variation of jet geometry with distance from the nozzle exit varies with the shape of the nozzle. Similar changes occur in both the density and temperature distributions. For the jet discharging into an ambient medium at rest, the mean pressure distribution remains almost constant everywhere, although, arising from the strong turbulent intensity in the turbulent mixing regions, the mean pressure in these mixing regions is slightly lower than ambient when the jet velocity is subsonic. When the jet velocity is supersonic the structure of the jet is controlled by a pattern of expansion and shock waves. It is only when the supersonic field of flow has decayed to subsonic velocities that the jet mixing region recovers the form of the subsonic jet.

Returning to the subsonic jet, the discussion so far has related to the mean rate of growth of the mixing regions upstream and downstream of the end of the potential core. The boundary of the turbulent jet is far from uniform and undulates randomly as it embraces the entrainment of irrotational flow from the ambient medium. The large eddy structure in the outer region of the jet reflects this entrainment, which increases linearly with distance downstream of the nozzle exit. Nevertheless in a frame of reference moving with the local averaged mean velocity, referred to as the mean convection velocity, we find it is sufficient to define averaged turbulent characteristic velocities and length scales, u_0 and ℓ_0 , respectively, which become only functions of the distance downstream of the nozzle

exit. These quantities can then be used to define the strength of the equivalent sound sources within the mixing layers. More complete data can be obtained by computing the distributions of k_T and ε_T , which are, respectively, the averaged turbulent kinetic energy and the rate of turbulent energy transfer, using steady flow RANS (Reynolds averaged Navier–Stokes equations) throughout the flow. Here we have put $k_T = u_0^2$ and $\varepsilon_T = u_0^3/\ell_0 = \omega_0 u_0^2$.

Under an assumption of flow similarity, which is supported by experimental observations in a high Reynolds number jet, u_0 becomes proportional to the local centerline mean velocity, and ℓ_0 becomes proportional to the local width of the mixing layer. Density fluctuations within the flow are normally neglected as they are small and have little influence on the properties of the mean flow. However, the effect of temperature fluctuations can never be neglected in heated turbulent flows. Even when the motion is supersonic and Mach waves are generated, which as described below can be analyzed by linear theory, the generation of sound still involves nonlinear processes. Lighthill's theory of aerodynamic noise describes the input required in order to evaluate the generation of noise in such a turbulent flow.

When the mixing regions are fully turbulent at a sufficiently high Reynolds number, for any given jet Mach number, and the flow is self-preserving, its average structure becomes independent of the jet Reynolds number, based on the nozzle diameter, and the jet velocity at the nozzle exit. Experiment suggests this jet Reynolds number, based on the jet exit conditions and the jet diameter, must exceed about 500,000 for turbulent flow independence to be achieved. This is a stringent condition, especially for hot jets in a laboratory simulation, since the high jet temperature generates a low jet density and increased molecular viscosity, with the result that the Reynolds number, for a given jet Mach number, is lowered. For details of recent laboratory experiments on the far-field noise of hot jets reference should be made to Viswanathan.³⁶

6 SIMPLE JET NOISE SCALING FORMULAS

The far-field pressure and density fluctuations are related by $p'(\mathbf{x}, t) = c_\infty^2 \rho'(\mathbf{x}, t)$. The acoustic intensity $I(\mathbf{x})$ is the average flux of acoustic power per unit area. It is given by

$$I(\mathbf{x}) = \frac{\langle p'^2 \rangle}{\rho_\infty c_\infty} = \frac{c_\infty^3}{\rho_\infty} \langle \rho'^2 \rangle \quad (29)$$

where $\langle \dots \rangle$ denotes the time average of a quantity. The source region is characterized by velocity and length scales u_0 and ℓ_0 , respectively, which are assumed to be functions of the distance downstream from the jet exit only. Lighthill's stress tensor is given by $\mathcal{T}_{xx} \sim \rho_0 u_0^2$ and the characteristic frequency ω_0 is determined from the turbulence Strouhal number, $s_T = \omega_0 \ell_0 / u_0$, which has a value based on measurements of about 1.7.

From Lighthill's solution, the sound intensity per unit volume of flow at a distance R from the nozzle exit is of the order

$$i(\mathbf{x}) \sim \frac{1.7^4}{16\pi^2 R^2 \ell_0 C_\theta^5} \frac{\rho_0^2}{\rho_\infty} u_0^3 m_0^5 \quad (30)$$

where the turbulence Mach number, with respect to the ambient speed of sound, is $m_0 = u_0/c_\infty$.

Consider first the early mixing region of a circular jet of diameter D_J , extending to the end of the potential core. The annular mixing region has nearly zero width at the nozzle exit and grows linearly over the potential core of length L . Its width at an axial distance $y_1 = L$ is assumed to be D_J . The average turbulent velocity fluctuation, u_0 , remains constant over the distance L , since u_0 is proportional to the mean velocity difference across the initial mixing region, which equals V_J , when the jet is exhausting into a medium at rest, having the density, ρ_∞ , and speed of sound, c_∞ . The average length scale of the turbulence, ℓ_0 , is proportional to the local width of the mixing region, $b(y_1)$. So $b(y_1) = y_1 D_J / L$ and we put $K = b/\ell_0$. In order to determine the total intensity Eq. (30) must be integrated over the average mixing region volume from $y_1 = 0$ to L . Since a slice of the mixing region has a volume of approximately $\pi D_J b(y_1) dy_1$,

$$I(\mathbf{x}) \sim \frac{1.7^4 K D_J^2}{16\pi R^2 C_\theta^5} \frac{\rho_0^2}{\rho_\infty} u_0^3 m_0^5 \frac{L}{D_J} \quad (31)$$

A similar integration is required for the jet downstream of the potential core, where the mixing region is growing linearly with y_1 , and the centerline velocity is decreasing inversely with y_1 . A constant property mixing region of approximate length $2D_J$ between the end of the potential core and the decaying jet downstream is also included. The contributions from the three regions are then added to obtain

$$I(\mathbf{x}) \sim \frac{1.7^4 K D_J^2}{16\pi R^2} \rho_J u_L^3 m_L^5 \left(\frac{L}{D_J} + 2 \right) \times \left(C_\theta^{-5} + \frac{1}{6} \frac{T_J}{T_\infty} \right) \quad (32)$$

where in the initial mixing region and the transition region we have assumed $\rho_0^2/\rho_\infty = \rho_\infty T_\infty/T_J$, and in the decaying region $\rho_0^2/\rho_\infty = \rho_\infty$. Then u_L and m_L are the values, respectively, of u_0 and m_0 at the end of the potential core and within the transitional region.

In this simple analysis the directivity is based on the effect of convective amplification on the radiated sound. The effects of refraction can be included approximately by using Snell's law, and assuming the existence of a zone of silence extending in the downstream direction to an angle θ_{cr} , from the jet axis. An approximate result for the total acoustic power in

watts, P is found from the integration of $I(\mathbf{x})$ over a sphere of radius R , leading to

$$P \sim \frac{1.7^4 K (\pi D_J^2/4)}{2} \rho_J u_L^3 m_L^5 \left(\frac{L}{D_J} + 2 \right) \times \int_{\theta_{cr}}^{\pi} \left(C_{\theta}^{-5} + \frac{1}{6} \frac{T_J}{T_{\infty}} \right) \sin \theta d\theta \quad (33)$$

Alternatively,

$$\frac{P}{L_P} = \frac{K 1.7^4}{\pi} \left(\frac{u_L}{V_J} \right)^8 \left(\frac{L}{D_J} + 2 \right) \times \int_{\theta_{cr}}^{\pi} \left(C_{\theta}^{-5} + \frac{1}{6} \frac{T_J}{T_{\infty}} \right) \sin \theta d\theta \quad (34)$$

where the jet operating conditions are expressed in the Lighthill parameter, $L_P = (\pi D_J^2/4) [(\frac{1}{2}) \rho_J V_J^3] M_J^5$, which is the mean energy flux at the jet exit multiplied by M_J^5 . The right-hand side embraces the mean geometry of the jet mixing region and its flow parameters.

The total acoustic power in decibels is given by $N(\text{dB re } 10^{-12} \text{ W}) = 120 + 10 \log_{10} P$. As an example, the total acoustic power from a jet of diameter $D_J = 0.025$ m, exhausting at $V_J = 340$ m/s, and a static temperature of 288 K, equals approximately $N(\text{dB}) = 132 \text{ dB re } 10^{-12} \text{ W}$, where it has been assumed that $K = 4.8$, $u_L/V_J = 0.2$, and $L/D_J = 5$. The half-angle of the zone of silence is $\theta_{cr} = 52^\circ$. The Lighthill parameter in this case is $L_P = 1.182 \times 10^4 \text{ W}$.

Estimates can also be made for the axial source strength distribution and the shape of the spectrum for the acoustic power. The axial source strength, the power emitted per unit axial distance, $dP(W)/dy_1$, can be found by multiplying the source intensity per unit volume by the source cross-sectional area, which, as given above, is $\pi D_J b(y_1)$ in the early mixing region and by $\pi b^2(y_1)$ in the jet downstream region. The source strength is constant in the initial mixing region and decays rapidly with seven powers of the axial distance in the downstream jet region. The acoustic power spectral density, the acoustic power per unit frequency, can be obtained by dividing the power per unit length of the jet by the rate of change of characteristic frequency with axial distance. That is $dP/d\omega = dP/dy_1 / |d\omega/dy_1|$. In the initial mixing region the characteristic frequency is inversely proportional to axial distance and in the downstream jet is inversely proportional to the square of axial distance. The acoustic power spectral density for the far-field noise from the entire jet is found in the low frequencies to increase as ω^2 and in the high frequencies to fall as ω^{-2} . These useful results show that the major contribution to the overall noise is generated in the

region just beyond the end of the potential core. In addition, the bulk of the high frequency noise generation comes from the initial mixing region and correspondingly the bulk of the low-frequency noise is generated downstream of the potential core, where the axial velocity is decaying to small values compared with the nozzle exit velocity. Of course, this refers to the dominant contributions to the noise generation, it being understood that at all stations in the jet the noise generation is broadband and covers the noise from both large- and small-scale energy-containing eddies.

These simple scaling laws form the basis for empirical jet noise prediction methods such as the SAE Aerospace Recommended Practice 876⁴⁶ and the methods distributed by ESDU International.⁴⁷ These methods include predictions for single and dual stream jets including the effects of forward flight and jet heating. To obtain the overall sound pressure level (OASPL) and one-third octave spectra for different observer angles, interpolation from an experimental database is used. An important contribution to the prediction of full-scale shock-free jet noise over a wide range of jet velocity and temperature, was made by Tam et al.⁴⁸ who showed, from a wide experimental database, that the jet noise spectrum at most angles to the jet axis could be represented by a combination of two universal spectra shown in Fig. 5. Figures 6 and 7 show how well these two spectra fit the experiments for a wide range of operating conditions near the peak noise directions ($\chi \approx 150^\circ$) and in the sideline direction ($\chi \approx 90^\circ$) where χ is the polar angle measured from the jet inlet axis. At intermediate angles the measured spectra can be fitted by a weighted combination of these two spectra. Tam et al.⁴⁸ used this excellent correlation as justification for the existence of two noise sources for

Figure 5 Similarity spectra for the two components of turbulent mixing noise. —, large turbulence structures/instability waves noise, $F(f/f_{\text{peak}})$; ---, fine-scale turbulence noise, $G(f/f_{\text{peak}})$. (From Tam et al.⁴⁸)

jet noise: a “large-scale” structure source and a “fine-scale” structure source. Though, as discussed below, this is likely to be a reasonable assumption at high speeds, its validity for subsonic jets has yet to be established. Additional comparisons of these similarity spectra with jet noise measurements, for both subsonic as well as supersonic jets, are given by Viswanathan.³⁶

The turbulent jet noise far-field acoustical spectra receive contributions from all regions of the jet with the major contributions being generated by the scales of turbulence near the energy-containing ranges. These scales range from extremely small close to the nozzle exit to extremely large far downstream. The acoustical spectrum for the complete jet is therefore very different from that generated locally at any downstream station of the jet, where it has many of the characteristics of local anisotropic or even isotropic turbulence. In the latter case, in the range of high frequencies far beyond the peak in the spectra, and therefore of the contribution made by the energy

Figure 7 Comparison of the similarity spectrum of fine-scale turbulence and measurements:

- (a) $M_j = 1.49$, $T_r/T_\infty = 2.35$, $\chi = 92.9^\circ$, $\text{SPL}_{\text{max}} = 96$ dB
- (b) $M_j = 2.0$, $T_r/T_\infty = 4.89$, $\chi = 83.8^\circ$, $\text{SPL}_{\text{max}} = 107$ dB

containing eddies, the laws for the decay of high-frequency noise can be represented by universal laws based on the local equilibrium theory of turbulence as found by Lilley.⁴⁹ To predict the noise radiation in more detail, additional analysis is needed. The details are beyond the scope of this chapter. They can be found in the original papers by Lighthill,^{1,3} Ffowcs Williams,⁶ and a review of classical aeroacoustics, with applications to jet noise, by Lilley.⁵⁰ The spectral density of the pressure in the far field is given by the Fourier transform of the autocorrelation of the far-field pressure. The instantaneous pressure involves an integral over the source region of the equivalent source evaluated at the retarded time, $\tau = t - R/c_\infty$. Thus the autocorrelation of the pressure must be related to the cross correlation of the source evaluated at emission times that would contribute to the pressure fluctuations at the observer at the same time. Since the Fourier transform of the source cross correlation is the source wavenumber–frequency spectrum, it is not surprising that it is closely related to the far-field spectral density. In fact, a rather simple relationship exists. Based on

Lighthill's acoustical analogy,

$$S(\mathbf{x}, \omega) = \frac{\pi \omega^4}{2 \rho_\infty c_\infty^5 R^2} \int_V H\left(\mathbf{y}, \frac{\omega \mathbf{x}}{c_\infty R}, \omega\right) d^3 \mathbf{y} \quad (35)$$

where $S(\mathbf{x}, \omega)$ is the spectral density at the observer location \mathbf{x} and frequency ω . $H(\mathbf{y}, \mathbf{k}, \omega)$ is the wavenumber–frequency spectrum at the source location \mathbf{y} and acoustic wavenumber \mathbf{k} . This apparently complicated mathematical result has a simple physical explanation.

The wavenumber–frequency representation of the source is a decomposition into a superposition of waves of the form $\exp[i(\mathbf{k} \cdot \mathbf{y} - \omega t)]$. To follow a point on one wave component, such as a wave crest, $\mathbf{k} \cdot \mathbf{y} - \omega t = \text{constant}$. The phase velocity of the wave is $d\mathbf{y}/dt$. But, from Eq. (35), only those wavenumber components with $\mathbf{k} = \omega \mathbf{x}/(c_\infty R)$ contribute to the radiated noise. The phase velocity in the direction of the observer is $(\mathbf{x}/R) \cdot (d\mathbf{y}/dt)$. Thus, only those waves whose phase velocity in the direction of the observer is equal to the ambient speed of sound ever escape the source region and emerge as radiated noise.

To proceed further it is necessary to provide a model for the source statistics. This can be a model for the two-point cross-correlation or the cross spectral density (see, Harper-Bourne⁵¹). The former is most often used. Detailed measurements of the two-point cross-correlation function of the turbulence sources have been attempted, but usually they are modeled based on measurements of correlations of the axial velocity fluctuation.* A typical measurement is shown

in Fig. 8. Each curve represents a different axial separation. As the separation distance increases, so the maximum correlation decreases. If the separation distances are divided by the time delays for the maximum correlation a nearly linear relationship is found. This gives the average convection velocity of the turbulence, $U_c = M_c c_\infty$. The envelope of the cross correlation curves represents the autocorrelation in a

T_{xx} and the wavenumber-frequency spectrum of the source. In their nondimensional form these space/time covariances were used to obtain the far-field acoustic intensity per unit flow volume in the mixing regions of the jet. The corresponding radiated power spectral density per unit volume of flow is then given by

$$p_{ac} = \left(\frac{4}{15} \pi\right) (\rho_\infty \langle u'^2 \rangle \omega^4 / c_\infty^5) \int_0^\infty r^4 dr \times \int_0^\infty \cos \omega \tau (\partial f(r, \tau) / \partial r)^2 d\tau \quad (36)$$

where $f(r, \tau)$ is the longitudinal velocity correlation coefficient in isotropic turbulence. Here r and τ are, respectively, the two-point space and retarded time separation variables. This model of the turbulence was used to calculate the total acoustic power from jets over a wide range of jet velocity and temperature using the distribution of turbulent kinetic energy, k_T , and the rate of energy transfer, ϵ_T , as determined by experiment and RANS calculations. The results of these computations are shown in Figs. 3 and 4 in comparison with experimental data. The numerical results for the total acoustic power thus differ slightly from those obtained from the simple scaling laws discussed above and the approximations using the Gaussian forms.

*In isotropic turbulence Lilley³⁹ used the DNS data of Sarkar and Hussaini⁵² to find the space/retarded time covariance of

Figure 8 Cross correlation of axial velocity fluctuations with downstream wire separation. Numbers on curves represent separation (in.). $Y/D = 0.5$, $X/D = 1.5$ (fixed wire). 1.0 in. = 2.54 cm. (From Davies et al.)⁵³

reference frame moving at the convection velocity. Various analytic functions have been used to model the cross-correlation function. The analysis is simplified if the temporal and spatial correlations are assumed to have a Gaussian form. But other functions provide a better fit to the experimental data.

The far-field spectral density is then found to be given by

$$S(\mathbf{x}, \omega) = \frac{1}{32\pi c_\infty^4 R^2} \int \rho_0^2 u_0^2 \ell_1 \ell_\perp^2 \omega_0^3 \frac{\omega^4}{\omega_0^4} \times \exp\left(-\frac{C_\theta^2 \omega^2}{4\omega_0^2}\right) d\mathbf{y} \quad (37)$$

For a compact source, $\omega_0 \ell_1 / c_\infty \ll 1$, and the modified Doppler factor reduces to the Doppler factor. However, at high speeds, this term cannot be neglected and is important to ensure that the sound field is finite at the Mach angle, $\cos^{-1}(1/M_c)$.

The OASPL directivity for the intensity is obtained by integration with respect to frequency, giving

$$I(x, \theta) = \frac{\langle (p')^2 \rangle(R, \theta)}{\rho_\infty c_\infty} = \frac{3}{4\sqrt{\pi} \rho_\infty c_\infty^5 R^2} \int \frac{\ell_1 \ell_\perp^2 \rho_0^2 u_0^4 \omega_0^4}{C_\theta^5} d\mathbf{y} \quad (38)$$

If ℓ_1 and ℓ_\perp are assumed to scale with ℓ_0 , then the intensity per unit volume of the turbulence is given by

$$i(x, \theta) \sim \frac{\rho_0^2}{\rho_\infty} \left(\frac{\ell_0}{R}\right)^2 \frac{u_0^5 m_0^3}{\ell_0^3} C_\theta^{-5} \quad (39)$$

which is in agreement with Eq. (30). C_θ^{-5} is called the convective amplification factor. It is due to the apparent change in frequency of the source, the Doppler effect, as well as effective change in the spatial extent of the source region. This latter effect is associated with the requirement that sources closer to the observer must radiate sound later than those farther from the observer to contribute to sound at the same time. During this time the convecting sources change their location relative to the observer. The net effect is that the sound is amplified if the sources are convecting toward the observer. This effect is described in detail by Ffowcs Williams.⁶

At 90° to the jet axis there is no convective amplification. Thus, a comparison of the noise spectra at any observer angle should be related to the 90° spectrum, when a Doppler frequency shift is also applied, through the convective amplification factor. Measurements (see, e.g., Lush³⁷) show this to be reasonably accurate at low frequencies, though there is generally an underprediction of the levels at small observer angles to the jet downstream axis. However, the peak frequency in the spectrum actually decreases

with decreasing observer angle (relative to the jet downstream axis), and convective amplification is apparently completely absent at high frequencies. The measurements show a “zone of silence” for observers at small angles to the jet downstream axis.

The zone of silence is due to mean flow/acoustical interaction effects. That is, sound that is radiated in the downstream direction is refracted away from the jet’s downstream axis. This is because the propagation speed of the wavefronts is the sum of the local sound speed and the local mean velocity. Thus, points on the wavefronts along the jet centerline travel faster than those away from the axis, and the wavefronts are bent away from the downstream direction. A similar effect, described by Snell’s law, is observed in optics. Though, in principle, Lighthill’s acoustical analogy accounts for this propagation effect, it relies on subtle phase variations in the equivalent sources that are difficult, if not impossible, to model. Lilley^{7,54} showed that linear propagation effects can be separated from sound generation effects if the equations of motion are rearranged so that the equivalent sources are at least second order in the fluctuations about the mean flow. This emphasizes the nonlinear nature of the sound generation process. Then, in the limit of infinitesimal fluctuations, the acoustical limit, the homogeneous equation describes the propagation of sound through a variable mean flow. Lilley showed that such a separation can be achieved for a parallel mean flow. That is, one in which the mean flow properties vary only in the cross stream direction. This is a good approximation to both free and bounded shear flows at high Reynolds numbers. The resulting acoustical analogy, which has been derived in many different forms, is known as Lilley’s equation. Its solution forms the basis for jet noise prediction methods that do not rely on empirical databases (see, e.g., Khavaran et al.⁵⁵).

In recent years, different versions of the acoustical analogy have been formulated. Goldstein⁵⁶ rearranged the Navier–Stokes equations into a set of inhomogeneous linearized Euler equations with source terms that are exactly those that would result from externally imposed shear stress and energy flux perturbations. He introduced a new dependent variable to simplify the equations and considered different choices of base flow. Morris and Farassat⁵⁷ argued that a simple acoustical analogy would involve the inhomogeneous linearized Euler equations as the sound propagator. This also simplifies the equivalent source terms. Morris and Boluriaan⁵⁸ derived the relationship between Green’s function of Lilley’s equation and Green’s functions for the linearized Euler equations. In a slight departure from the fundamental acoustical analogy approach, Tam and Auriault⁵⁹ argued that the physical sources of sound are associated with fluctuations in the turbulent kinetic energy that causes local pressure fluctuations. Then the gradient of the pressure fluctuations are the acoustic sources. Again, the sound propagation was calculated based on the linearized Euler equations. It is expected that new versions of the original acoustical

analogy will be developed. This is because the acoustical analogy approach offers a relatively inexpensive method of predicting the radiated noise from a limited knowledge of the turbulent flow, such as a steady Computational Fluid Dynamics (CFD) solution. However, it has yet to be shown that these approaches can be used with confidence when subtle changes in the flow are made, such as when “chevrons” or “serrations” are added to the jet nozzle exhaust. In such cases, either extensive measurements or detailed CAA (as described below) may be necessary.

7 SUPERSONIC JET NOISE

As the speed of the jet increases, both the structure of the jet and the noise radiation mechanisms change. Ffowcs Williams⁶ used Lighthill’s acoustical analogy to show that the eighth velocity power law scaling for the intensity changes to a velocity cubed scaling when the jet velocity significantly exceeds the ambient speed of sound, as shown in Fig. 1. However, at these high speeds, two new phenomena become important for noise generation and radiation. The first is related to the supersonic convection of the turbulent large-scale structures and the second is related to the presence of shock cells in the jet when operating off-design. The physical mechanism of turbulent shear layer-shock interaction and the consequent generation of shock noise is complex. Contributions to its understanding have been given experimentally by Westley and Wooley⁶⁰ and Panda,⁶¹ and theoretically by Ribner⁶² and Manning and Lele.⁶³ A review of supersonic jet noise is provided by Tam.⁶⁴

7.1 Noise from Large-Scale Structures/Instability Waves

The experiments of Winant and Browand⁶⁵ and Brown and Roshko⁶⁶ were the first to demonstrate that the turbulent mixing process in free shear flows is controlled by large-scale structures. These large eddies engulf the ambient fluid and transport it across the shear layer. Similarly, high-speed fluid is moved into the ambient medium. This is different from the traditional view of turbulent mixing involving random, small eddies, performing mixing in a similar manner to molecular mixing. Though it was first thought that these large-scale structures were an artifact of low Reynolds number transitional flows, subsequent experiments by Papamoschou and Roshko,⁶⁷ Lepicovsky, et al.,⁶⁸ and Martens et al.,⁶⁹ demonstrated their existence for a wide range of Reynolds and Mach numbers. Experiments (see, e.g., Gaster et al.⁴⁴) also showed that the characteristics of the large-scale structures were related to the stability characteristics of the mean flow. A turbulence closure scheme based on this observation was developed by Morris et al.⁴⁵ Such so-called instability wave models have also been used to describe the large-scale turbulence structures in shear layers and jets and their associated noise radiation (see, e.g., Tam⁷⁰ and Morris⁷¹).

A complete analysis of the noise radiation by large-scale turbulence structures in shear layers and

jets at supersonic speeds, and comparisons with measurements, is given by Tam and Morris⁷² and Tam and Burton.⁷³ The analysis involves the matching of a near-field solution for the large-scale structures with the radiated sound field using the method of matched asymptotic expansions. However, the basic physical mechanism is easily understood in terms of a “wavy wall analogy.” It is well known that if a wall with a small-amplitude sinusoidal oscillation in height is moved parallel to its surface then, if the speed of the surface is less than the ambient speed of sound in the fluid above the wall, the pressure fluctuations decay exponentially with distance from the wall. However, if the wall is pulled supersonically, then Mach waves are generated and these waves do not decay with distance from the wall (in the plane wall case). These Mach waves represent a highly directional acoustic field. The direction of this radiation, relative to the wall, is given by $\theta = \cos^{-1}(1/M)$, where M is the wall Mach number. This is another manifestation of the requirement that for sound radiation to occur the source variation must have a phase velocity with a component in the direction of the observer that is sonic. In the case of the turbulent shear flow, the large-scale structures, that are observed to take the form of a train of eddies, generate a pressure field that is quasi-periodic in space and convects with a velocity of the order of the mean flow velocity. At low speeds, the pressure fluctuations generated by the wave train are confined to the near field. However, when the convection velocity of the structures is supersonic with respect to the ambient speed of sound, they radiate sound directly to the far field. The result is a highly directional sound radiation pattern. Figure 9 shows a comparison

Figure 9 Comparison of predicted far-field directivity calculations for a cold Mach 2 jet with measured data. Predictions based on an instability wave model for the large-scale structures and their radiated noise. Strouhal number = 0.2. (From Dahl⁷⁵ with permission. Data from Seiner and Ponton.⁷⁴)

of the predicted directivity, based on an instability wave model, with measurements. The agreement is excellent in the peak noise direction. At larger angles to the downstream axis the predictions fall below the measurements. At these angles, the subsonic noise generation mechanisms are more efficient than the instability wave radiation.

Though the evidence is strongly in favor of large-scale structure or instability wave radiation at supersonic convection velocities being the dominant noise source, it does not provide a true prediction capability. This is because the analysis to this time has been linear. So absolute noise radiation levels are not predicted: just the relative levels. An aeroacoustics problem that has been fully represented by an instability wave model is the excitation of jets by sound. Tam and Morris⁷⁶ modeled the acoustical excitation of a high Reynolds number jet. The complete model includes a "receptivity" analysis, which determines to what level the instability wave is excited by the sound near the jet exit, the calculation of the axial development of the instability wave, based on linear instability analysis, and the interaction between the finite amplitude instability wave and the small-scale turbulence. The agreement with experiment was excellent, providing strong support for the modeling of the large-scale structures as instability waves.

7.2 Shock-Associated Noise

The large-scale structures, modeled as instability waves, also play an important role in shock-associated noise. Shock-associated noise occurs when a supersonic jet is operating "off-design." That is, the pressure at the nozzle exit is different from the ambient pressure. For a converging nozzle, the exit pressure is always equal to the ambient pressure when the pressure ratio (the ratio of the stagnation or reservoir to the ambient pressure) is less than the critical value of $[1 + (\gamma - 1)/2]^{1/(\gamma - 1)}$, where γ is the specific heat ratio. The ratio is 1.893 for air at standard temperature. Above this pressure ratio the converging nozzle is always "under expanded." Converging-diverging nozzles can be either under- or overexpanded. When a jet is operating off-design, a shock cell system is established in the jet plume. This diamond-shaped pattern of alternating regions of pressure and temperature can often be seen in the jet exhaust flow of a military jet aircraft taking off at night or in humid air conditions.

Pack⁷⁷ extended a model first proposed by Prandtl that describes the shock cell structure, for jets operating close to their design condition, with a linear analysis. If the jet is modeled by a cylindrical vortex sheet, then inside the jet the pressure perturbations satisfy a convected wave equation. The jet acts as a waveguide that reflects waves from its boundary. This is a steady problem in which the waveguide is excited by the pressure mismatch at the nozzle exit. This simple model provides a very good approximation to the shock cell structure. Tam et al.⁷⁸ extended the basic model to include the effects of the finite thickness of the jet shear layer and its growth in the axial direction.

They showed excellent agreement with measurements of the shock cell structure. Morris et al.⁷⁹ applied this model to jets of arbitrary exit geometry.

Fig. 10 shows a jet noise spectrum measured at 30° to the jet inlet direction. Three components are identified. The jet mixing noise occurs at relatively low frequencies and is broadband with a peak Strouhal number of approximately $S_t = 0.1$. Also identified are broadband shock noise and screech. These noise mechanisms and models for their prediction are described next.

The first model for shock-associated noise was developed by Harper-Bourne and Fisher.⁸¹ They argued that it was the interaction between the turbulence in the jet shear layer and the quasi-periodic shock cell structure that set a phased array of sources at the locations where the shock cells intersected the shear layer. Tam and Tanna⁸² developed a wave model for this process. Let the axial variation of the steady shock cell structure pressure p_s in the jet be modeled, following Pack,⁷⁷ in terms of Fourier modes. The amplitude of the modes is determined by the pressure mismatch at the jet exit. That is, let

$$p_s = \sum_{n=0}^{\infty} a_n \exp(ik_n x) + \text{complex conjugate} \quad (40)$$

where $2\pi/k_n$ is the wavelength of the n th mode. So, $2\pi/k_1$ gives the fundamental shock cell spacing, L_1 . Let the pressure perturbations p_t , associated with the shear layer turbulence, be represented by traveling waves of frequency ω and wavenumber α . That is,

$$p_t = b_n \exp[i(\alpha x - \omega t)] + \text{complex conjugate} \quad (41)$$

Figure 10 Typical far-field narrow-band supersonic jet noise spectrum level showing the three components of supersonic jet noise: turbulent mixing noise, broadband shock-associated noise, and screech 1-Hz bandwidth. (From Tam.⁶⁴) (Data from Seiner.⁸⁰)

A weak interaction between the steady and traveling wave patterns generates an interference pattern $p_i \sim p_s \times p_t$, where

$$p_i \sim a_n b_n \exp\{i[(\alpha + k_n)x - \omega t]\} + a_n b_n^* \exp\{-i[(\alpha - k_n)x - \omega t]\} + \text{complex conjugate} \quad (42)$$

The phase velocity of the traveling wave given by the first term in (42) is given by $\omega/(\alpha + k_n)$. Thus, this pattern travels more slowly than the instability wave and will only generate sound at very high jet velocities. The wave represented by the second term has a phase velocity of $\omega/(\alpha - k_n)$. Clearly, this is a very fast wave pattern and can even have a negative phase velocity so that it can radiate sound to the forward arc.

As noted before, for sound radiation to occur, the phase velocity of the source must have a sonic component in the direction of the observer. Let the observer be at a polar angle θ relative to the downstream jet axis. Then, for sound radiation to occur from the fast moving wave pattern,

$$\frac{\omega \cos \theta}{\alpha - k_n} = c_\infty \quad (43)$$

If the phase velocity of the instability wave or large-scale turbulence structures is $u_c = \omega/\alpha$, then the radiated frequency is given by

$$f = \frac{u_c}{L_1 (1 - M_c \cos \theta)} \quad (44)$$

where $M_c = u_c/c_\infty$. It should be remembered that the turbulence does not consist of a single traveling wave but a superposition of waves of different frequencies moving with approximately the same convection velocity. Thus, the formula given by (44) represents how the peak of the broadband shock-associated noise varies with observer angle. Based on this modeling approach, Tam⁸³ developed a prediction scheme for broadband shock-associated noise. It includes a finite frequency bandwidth for the large-scale structures. An example of the prediction is shown in Fig. 11. The decrease in the peak frequency of the broadband shock-associated noise with increasing angle to the jet downstream axis is observed. Note that the observer angles in the figure are measured relative to the jet inlet axis: a procedure used primarily by aircraft engine companies. As the observer moves toward the inlet, the width of the shock-associated noise spectrum decreases, in agreement with the measurements. Also noticeable is a second oscillation in the noise spectrum at higher frequencies. This is associated with the interaction of the turbulence with the next Fourier mode representing the shock cell structure.

Screech tones are very difficult to predict. Though the frequency of the screech tones are relatively easy to predict, their amplitude is very sensitive to the details of the surrounding environment. Screech tones were first observed by Powell.^{85,86} He recognized that the

Figure 11 Comparison between calculated broadband shock noise spectrum levels and measurements of Norum and Seiner.⁸⁴ Predictions based on stochastic model for broadband shock-associated noise of Tam,⁸³ 40-Hz bandwidth. (From, Tam.⁶⁴)

tones were associated with a feedback phenomenon. The components of the feedback loop involve the downstream propagation of turbulence in the jet shear layer, its interaction with the shock cell structure, which generates an acoustic field that can propagate upstream, and the triggering of shear layer turbulence due to excitation of the shear layer at the nozzle lip. Tam et al.⁸⁷ suggested a link between broadband shock-associated noise and screech. It was argued that the component of broadband shock-associated noise that travels directly upstream should set the frequency of the screech. Thus, from (1.44), with $\theta = \pi$, the screech frequency f_s is given by

$$f_s = \frac{u_c}{L_1} \frac{1}{1 + M_c} \quad (45)$$

An empirical frequency formula, based on $u_c \approx 0.7$ and accounting for the fact the shock cell spacing is approximately 20% smaller than that given by the vortex sheet model, is given by Tam.⁶⁴

$$\frac{f_s d_j}{U_j} = 0.67 (M_j^2 - 1)^{-1/2} \left[1 + 0.7 M_j \times \left(1 + \frac{\gamma - 1}{2} M_j^2 \right)^{-1/2} \left(\frac{T_r}{T_\infty} \right)^{1/2} \right]^{-1} \quad (46)$$

Figure 12 Comparisons between measured⁸⁸ and calculated⁸⁷ screech tone frequencies at different total temperature T_r . (From Tam.⁶⁴)

where T_r and T_∞ are the jet reservoir and the ambient temperature, respectively. Figure 12 shows a comparison of the calculated screech tone frequencies based on (46) and the measurements by Rosfjord and Toms⁸⁸ for different temperature jets. The agreement is very good. Tam⁸⁹ extended these ideas to give a formula for screech frequency tones in a rectangular jet. Morris⁹⁰ included the effects of forward flight on the shock cell spacing and screech frequencies, and Morris et al.⁷⁹ performed calculations for rectangular and elliptic jets. In all cases the agreement with experiment was good.

Full-scale hot jets show less ability to screech than laboratory cold jets at similar pressure ratios. This was observed on the Concorde. However, screech tones can occur at full scale and be so intense that they can result in structural damage. Intense pressure levels have been observed in the internozzle region of twin supersonic jets. This is the configuration found in the F-15 jet fighter. Seiner et al.⁹¹ describe the resulting sonic fatigue damage. They also conducted model experiments. Tam and Seiner⁹² and Morris⁹³ studied the instability of twin supersonic jets as a way to understand the screech mechanisms.

Numerical simulations of jet screech have been performed by Shen and Tam.^{94,95} They examined the effect of jet temperature and nozzle lip thickness on the screech tone frequencies and amplitude. Very good agreement was achieved with measurements by Ponton and Seiner.⁹⁶ These simulations are an example of the relatively new field of computational aeroacoustics

(CAA). A very brief introduction to this area is given in the next section.

Military aircraft powered by jet engines and rocket motors, the launchers of space vehicles, and supersonic civil transports, can have a jet exit Mach number sufficiently large for the eddy convection Mach number to be highly supersonic with respect to the ambient medium. Such very high speed jets generate a phenomenon known as “crackle.” This arises due to the motion of supersonic eddies that, during their lifetime, create a pattern of weak shock waves attached to the eddy, having the character of a sonic boom as discussed in Section 3. Thus, in the direction normal to the shock waves, the propagating sound field external to the jet comprises an array of weak sonic booms and is heard by an observer as a crackle. Further details of this phenomenon are given by Ffowcs Williams et al.⁹⁷ and Petitjean et al.⁹⁸

8 COMPUTATIONAL AEROACOUSTICS

With the increased availability of high-performance computing power, the last 15 years have seen the emergence of the field of computational aeroacoustics (CAA). This involves the direct numerical simulation of both the unsteady turbulent flow and the noise it generates. Excellent reviews of this new field have been given by Tam,⁹⁹ Lele,¹⁰⁰ Bailly and Bogey,¹⁰¹ Colonius and Lele,¹⁰² and Tam.¹⁰³ In addition, an issue of the *International Journal of Computational Fluid Dynamics*¹⁰⁴ is dedicated to issues and methods in CAA.

There are several factors that make CAA far more challenging than traditional computational fluid dynamics (CFD). First, the typical acoustic pressure fluctuation is orders of magnitude smaller than the mean pressure or the fluctuations in the source region. Second, acoustic wave propagation is both nondispersive and nondissipative (except when atmospheric absorption effects are included). The range of frequencies generated in, for example, jet noise, cover at least two decades. Also, aeroacoustics is a multiscale phenomenon, with the acoustic wavelengths being much greater than the smallest scales of the turbulence. This is especially important, as most aeroacoustic problems of practical interest involve turbulence at high Reynolds numbers. Finally, acoustic radiation usually occurs in unbounded domains, so nonreflecting boundary treatments are essential.

The requirements of high accuracy and low dispersion and dissipation have resulted in the use of high-order discretization schemes for CAA. Spectral and pseudospectral schemes have been widely used for turbulence simulation in simple geometries. They have also been used in CAA¹⁰⁵ to compute the near field with the far field being calculated with an acoustical analogy formulation. Finite element methods have also been used. In particular, the discontinuous Galerkin method^{106,107} has become popular. The advantage of this method is that the discretization is local to an individual element and no global matrix needs to be constructed. This makes their implementation on parallel computers particularly efficient. The most popular

methods for spatial discretization have been finite difference methods. These include compact finite difference methods¹⁰⁸ and the dispersion-relation-preserving (DRP) schemes introduced by Tam and Webb.¹⁰⁹ The latter method optimizes the coefficients in a traditional finite-difference scheme to minimize dispersion and dissipation. CAA algorithms are reviewed by Hixon.¹¹⁰

Boundary conditions are very important as the slightest nonphysical reflection can contaminate the acoustical solution. In addition, nonreflecting boundary conditions must allow for mean entrainment of ambient fluid by the jet. Without this, the axial evolution of the jet would be constrained. An overview of boundary conditions for CAA is given by Kurbatskii and Mankbadi.¹¹¹ Boundary conditions can be either linear or nonlinear in nature. Among the linear methods, there are characteristic schemes such as a method for the Euler equations by Giles,¹¹² and methods based on the form of the asymptotic solution far from the source region, such as given by Bayliss and Turkel¹¹³ and Tam and Webb.¹⁰⁹ The perfectly matched layer (PML) was first introduced in electromagnetics by Berenger¹¹⁴ and adapted to the linearized Euler equations by Hu.¹¹⁵ Hu¹¹⁶ has made recent improvements to the method's stability. The PML involves a buffer domain around the computational domain in which the outgoing sound waves are damped. Nonlinear methods include the approximate multidimensional characteristics-based schemes by Thompson,^{117,118} as well as buffer zone techniques, originally introduced by Israeli and Orszag,¹¹⁹ and also implemented by Freund¹²⁰ and Wasistho et al.¹²¹ among many others. Absorbing boundary conditions are reviewed by Hu.¹²²

Finite difference discretization of the equations of motion generally yields two solutions. One is the longer wavelength solution that is resolved by the grid. The second is a short wavelength solution that is unresolved. The short wavelength solutions are called spurious waves. These waves can be produced at boundaries, in regions of nonuniform grid, and near discontinuities such as shocks. They can also be generated by the nonlinearity of the equations themselves, such as the physical transfer of energy from large to small scales in the Navier-Stokes equations, and by poorly resolved initial conditions. Various approaches have been taken to eliminate these spurious waves. These include the use of biased algorithms,¹²³ the application of artificial dissipation,^{109,124} and explicit or implicit filtering.¹²⁵ Whatever method is used, care must be taken not to dissipate the resolved, physical solution.

Many of the difficulties faced in CAA stem from the turbulent nature of source region. Clearly, if the turbulence cannot be simulated accurately, the associated acoustic radiation will be in error. The direct numerical simulation (DNS) of the turbulence is limited to relatively Reynolds numbers as the ratio of largest to the smallest length scales of the turbulence is proportional to $Re^{3/4}$. Thus the number of grid points required for the simulation of one large-scale eddy is at least $Re^{9/4}$.

Freund¹²⁶ performed a DNS of a $Re_D = 3.6 \times 10^3$ jet at a Mach number of 0.9 and used 25.6×10^6 grid points. To simulate higher Reynolds turbulent flows either large eddy simulation (LES) or detached eddy simulation (DES) has been used. In the former case, only the largest scales are simulated and the smaller, subgrid scales are modeled. Examples include simulations by Bogey et al.,¹²⁷ Morris et al.,¹²⁸ and Uzun et al.¹²⁹ DES was originally proposed for external aerodynamics problems by Spalart et al.¹³⁰ This turbulence model behaves like a traditional Reynolds-averaged Navier-Stokes (RANS) model for attached flows and automatically transitions to an LES-like model for separated flows. The model has been used in cavity flow aeroacoustic simulations,¹³¹ and in jet noise simulations.^{132,133} All of these simulations involve large computational resources and the computations are routinely performed on parallel computers. A review of parallel computing in computational aeroacoustics is given by Long et al.^{134*}

Early studies in CAA emphasized the propagation of sound waves over large distances to check on the dispersion and dissipation characteristics of the algorithms. However, more recent practical applications have focused on a detailed simulation of the turbulent source region and the near field. The far field is then obtained from the acoustical analogy developed by Ffowcs Williams and Hawkins.⁵ This analogy was developed with applications in propeller and rotorcraft noise in mind. It extends Lighthill's acoustic analogy to include arbitrary surfaces in motion. Its application in propeller noise is described in Chapter 90 of this handbook. The source terms in the Ffowcs Williams-Hawkins (FW-H) equation include two surface sources in addition to the source contained in Lighthill's equation (17). In propeller and rotorcraft noise applications these are referred to as "thickness" and "loading noise." However, the surfaces need not correspond to physical surfaces such as the propeller blade. They can be permeable. The advantage of the permeable surface formulation is that if all the sources of sound are contained within the surface, then the radiated sound field is obtained by surface integration only. Brentner and Farassat¹³⁵ have shown the

*The attempts to find time-accurate calculations of a turbulent flow at moderate to high Reynolds numbers for noise predictions have shown that, outside the range of DNS calculations, the range of frequencies covered is restricted, arising from computer limitations, when compared with the noise spectra from the aircraft propulsion engines in flight. It appears that the turbulence model equations used for the averaged properties in a steady flow are less reliable when used for the unsteady time-accurate properties and calibration of unsteady methods poses many difficult problems. Hence the need continues to exist for acoustical models based on the steady-state averaged turbulence quantities in noise prediction methods, where the methods need to be carefully calibrated against experimental data. Emphasis should also be placed on modeling the noise generated by the unresolved scales of turbulence in LES and DES.

general relationship between the FW-H equation and the Kirchhoff equation (see Farassat and Myers¹³⁶). di Franciscantonio¹³⁷ implemented the permeable surface form of the FW-H equation for rotor noise prediction. The advantage of the FW-H equation, clearly demonstrated by Brentner and Farassat, is that it is applicable to any surface embedded in a fluid that satisfies the Navier-Stokes equations. On the other hand, the Kirchhoff formulation relies on the wave equation being satisfied outside the integration surface. Brentner and Farassat¹³⁵ show examples where noise predictions based on the Kirchhoff formulation can be in error by orders of magnitude in cases where nonlinear effects are present outside the integration surface. Examples include situations where a wake crosses the surface, such as in calculations of noise radiated by a cylinder in uniform flow, or in the presence of shocks, such as occur in transonic flow over a rotor blade. Most recent CAA noise predictions have used the FW-H formulation.

9 BOUNDARY LAYER NOISE

In this section, the noise radiated from external surface boundary layers is discussed. The noise radiated from internal boundary layers in ducts is a separate problem and reference should be made to later chapters in this handbook. Here applications of aerodynamic noise theory to the noise radiated from the boundary layers developing over the upper and lower surfaces of aircraft wings and control surfaces are considered. This forms a major component of airframe noise, which together with engine noise contribute to aircraft noise as heard on the ground in residential communities close to airports. At takeoff, with full engine power, aircraft noise is dominated by the noise from the engine. But, on the approach to landing at low flight altitudes, airframe and engine noise make roughly equal contributions to aircraft noise. Thus, in terms of aircraft noise control it is necessary to reduce both engine and airframe noise for residents on the ground to notice a subjective noise reduction. Methods of airframe noise control are not discussed in detail in this section and the interested reader should refer to the growing literature on this subject. A review of airframe noise is given by Crighton.¹³⁸ The complexity of the various boundary layers and their interactions on an aircraft forming its wake is shown in Fig. 13.

The structure of the turbulent compressible boundary layer varies little from that of the boundary layer in an incompressible layer. The distribution of the mean flow velocity, however, changes from that in an incompressible flow due to the variation of the mean temperature and mean density for a given external pressure distribution. At low aircraft flight Mach numbers the boundary layer density fluctuations relate directly to the pressure fluctuations. The presence of sound waves represents a very weak disturbance in turbulent boundary layers and does not greatly modify the structure of the pressure fluctuations as measured in incompressible flows. The wall pressure fluctuations under a turbulent boundary layer are often referred to as boundary layer noise, or pseudonoise, since they are measured

Figure 13 Structure of the wake downstream of high-lift extended flaps (photograph using the Wake Imaging System). (From Crowder.¹³⁹)

by pressure transducers and microphones. However, they are defined here as flow pressure fluctuations and not noise. Turbulent boundary layer noise refers to the propagation of noise emerging out of a boundary layer and radiated to an observer in the acoustic far field. Steady flow laminar boundary layers do not generate noise, but this is not true of the region of transition between laminar and fully developed turbulent flow, where the flow is violently unsteady. Here, only the case where the turbulence in the boundary layer commences at the wing leading edge is considered. Let us first consider the radiation from the region of the boundary layer remote from the leading and trailing edges, where it can be assumed that the boundary layer is part of an idealized infinite flat plate having no edges.

9.1 Noise Radiation from an Infinite Flat Plate

For a rigid flat plate the governing wave equation for this theoretical problem is called the Lighthill-Curle equation. In this case the radiated sound field is shown to be a combination of quadrupole noise generated by the volume distribution of the Reynolds stresses in \mathcal{T}_{ij} , and the dipole noise generated by the distribution of surface stresses p_{ij} . For the infinite plate, the source distribution resulting from a turbulent flow is clearly noncompact. For the infinite plate it was found by Phillips¹⁴⁰ and Kraichnan¹⁴¹ that the strength of the total dipole noise was zero due to cancellation by the image sound field. The quadrupole noise is, however, doubled by reflection from the surface, as found by Powell.¹⁴² It has been shown by Crighton¹⁴³ and Howe¹⁴⁴ that, for upper surface sources not close to the edge of a half-plane, the sound radiation is upward and quadrupole, similar to that occurring with the infinite plate. Equivalent sound sources in a boundary layer on the lower surface radiate downward, and the radiation is quadrupole, for sources not close to the edge. Thus, for an aircraft, the sound radiation from the normal surface pressure fluctuations over the wing are negligible, in spite of the large surface wing area, compared with (i) the noise radiated from the jet of

the propulsion engines, since in the jet the turbulence intensity is much greater, and (ii) the diffracted noise radiated from the wing trailing edge, as will be shown below.

9.2 The Half-Plane Problem

The propagation of sound waves from sources of sound close to a sharp edge behave differently from sound propagating from the equivalent sources of sound in free turbulence. The pressure field close to a sound source, and within a wavelength of that source, becomes amplified by the proximity to the edge. The edge then becomes the origin for a diffracted sound field, which is highly amplified compared with that generated by free turbulence. In the pioneering work of Ffowcs Williams and Hall,⁹ the aeroplane wing is replaced by a half-plane with its sharp trailing edge representing the scattering edge. The theory is similar to that in electromagnetic diffraction theory introduced by Macdonald.¹⁴⁵ In this representation of the theory there is no flow. However, subsequent work by Crighton¹⁴³ and Howe¹⁴⁴ and others has shown that the theory can be applied to moving sources crossing the edge, which can be interpreted as representing turbulence crossing the wing trailing edge from the boundary layer into the wake. Therefore, Lighthill's theory, as used in the theory of free turbulence, as modified in the Lighthill–Curle theory to include the flow over a plane surface, and now further modified by Ffowcs Williams and Hall⁹ to include the effect of the finite wing trailing edge, can be used. The theory is similar to that of Lighthill, but instead of the free-field Green's function a special Green's function is used that has its normal derivative zero on the half-plane, and represents an outgoing wave in the far field. It is found that with this Green's function the surface contribution to the far-field noise involves only viscous stresses and at high Reynolds numbers their contribution is negligible. In most applications to aircraft noise the lower surface boundary layer is much thinner than the upper surface boundary layer and hence the greater contribution to the noise below the aircraft arises from the upper surface boundary layer as its pressure field is scattered at the wing trailing edge, and the sound radiated is diffracted to the observer. Thus following Goldstein¹⁰ the acoustic field is given by,

$$(\rho - \rho_\infty)(\mathbf{x}, t) \sim \frac{1}{c_\infty^2} \int \frac{\partial^2 G}{\partial y_i \partial y_j} \mathcal{T}_{ij}^* dy + \frac{1}{c_\infty^2} \int \frac{\partial G}{\partial y_i} f_i^* dS(\mathbf{y}) \quad (47)$$

where dy represents an elemental volume close to the edge of the half-plane, f_i are the unsteady forces acting on the surface $S(\mathbf{y})$, and the asterisk denotes evaluation at the retarded or emission time, $t - R/c_\infty$. The distribution of sound sources per unit volume is proportional to \mathcal{T}_{ij} , but their contribution to the far-field sound is now enhanced compared with that in free turbulence, since (i) they no longer appear with

derivatives, and (ii) the term involving the derivatives of the Green's function is singular at the edge.

The Green's function, G for the half-plane, satisfies the boundary condition that $\partial G / \partial y_2 = 0$ on $y_1 > 0$ and $y_2 = 0$. The outgoing wave Green's function for the Helmholtz equation G_ω is related to the Green's function G by (see Goldstein,¹⁰ page 63):

$$G(\mathbf{x}, t | \mathbf{y}, \tau) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp[-i\omega(t - \tau)] G_\omega(\mathbf{x}, \mathbf{y}) d\omega \quad (48)$$

Its far-field expansion is given by

$$G_\omega = \frac{1}{4\pi} \left[\frac{e^{ikx}}{x} F(a) + \frac{e^{ikx'}}{x'} F(a') \right] \quad (49)$$

where x and x' are, respectively, the distances between the stationary observer at \mathbf{x} and the stationary source at \mathbf{y} above the plane and its image position \mathbf{y}' below the plane. $k = \omega/c_\infty$ is the free space wavenumber. $F(a)$ is the Fresnel integral,* and since acoustic wavenumbers are small for typical frequencies of interest in problems of aircraft noise, it follows that the Fresnel integral is approximately equal to $a/\sqrt{\pi}$. Note that this special Green's function is simply the sum of two free-field Green's functions, each weighted by Fresnel integrals. It follows that the diffracted sound field below an aircraft has a distinct radiation pattern of cardioid shape, which is almost independent of the turbulent sound sources.

The solution to Lighthill's integral in the frequency domain is

$$\tilde{\rho} = \frac{1}{c_\infty^2} \int \frac{\partial^2 G_\omega}{\partial y_i \partial y_j} \tilde{\mathcal{T}}_{ij} dy \quad (52)$$

where $\tilde{\mathcal{T}}_{ij}$ is the Fourier transform of \mathcal{T}_{ij} . On introducing the approximation to the Fresnel integrals

*The Fresnel integral is given by

$$F(a) = \frac{1}{2} + \frac{e^{i\pi/4}}{\sqrt{\pi}} \int_a^\infty e^{iu^2} du \quad (50)$$

where the diffraction parameters for the source and its image are, respectively,

$$a = (2kr_0 \sin \theta)^{1/2} \cos\left[\frac{1}{2}(\phi - \phi_0)\right] \\ a' = (2kr_0 \sin \theta)^{1/2} \cos\left[\frac{1}{2}(\phi + \phi_0)\right] \quad (51)$$

The source position is given in cylindrical coordinates (r_0, ϕ_0) relative to the edge, while the line from the origin on the edge to the observer is given in terms of the angles (θ, ϕ) . For sources close to the plane the differences between R and R' in the far field can be ignored.

for small values of a , and noting that for a given frequency ω

$$a + a' = \frac{(2\omega \sin \theta)^{1/2}}{c_\infty^{1/2}} r_0^{1/2} \cos\left(\frac{\phi}{2}\right) \cos\left(\frac{\phi_0}{2}\right) \quad (53)$$

where the distance from the edge to the sound source at \mathbf{y} is $r_0 = \sqrt{y_1^2 + y_2^2}$ and $\tan \phi_0 = y_2/y_1$, it is found that for all frequencies of the turbulent fluctuations, the Fourier transform of the far-field density has a proportionality with $\omega^{1/2}$. When the averaged values of the T_{ij} covariance are introduced, the far-field sound intensity per unit flow volume is accordingly

$$i(\mathbf{x}) \sim \frac{1}{2\pi^3} \frac{\rho_\infty \omega_0 u_0^4}{c_\infty^2 R^2} \left(\frac{\ell_0}{r_0}\right)^2 \sin \theta \cos^2\left(\frac{\phi}{2}\right) \quad (54)$$

Clearly, the distance of the source from the edge, r_0 is of the order of the scale of the turbulence, ℓ_0 . However, it should be recalled that the turbulence covers a wide range of scales and frequencies and all such sources are compact with $\ell_0/\lambda \ll 1$, even when $\ell = \delta$, the boundary layer thickness, where the acoustic wavelength, $\lambda = 2\pi c_\infty/\omega$. The theory is valid when $kr_0 \ll 1$. If the scale of the turbulence is ℓ_0 , equal to the integral scale, which is assumed to be the scale of the energy containing eddies, then $\omega \ell_0/u_0 = s_T$, where the turbulence Strouhal number, $s_T = 1.7$, approximately. It is found that, for all frequencies of interest in aircraft noise problems, $kr_0 \ll 1$.

9.3 Frequency Spectrum of Trailing Edge Noise

From dimensional reasoning, the high-frequency local law of decay can be found in the inertial subrange of the turbulence. First, the acoustic power spectral density per unit volume of turbulence, \tilde{p}_s , is given by

$$\tilde{p}_s \sim \frac{2}{\pi^2} \frac{\rho_\infty}{c_\infty^2} F(\varepsilon_T, \omega) \quad (55)$$

since the spectral density at high frequencies depends only on the frequency, ω , and the rate of energy transfer, ε_T . It follows that $F(\varepsilon_T, \omega)$ has the dimensions of the fourth power of the velocity. Dimensional analysis shows that

$$F(\varepsilon_T, \omega) = \beta \left(\frac{\varepsilon_T}{\omega}\right)^2 \quad (56)$$

But since $\varepsilon_T = v\omega_s^2$ with $\omega_s = u_s/\ell_s$ and $u_s \ell_s/v = 1$ (where the subscript s denotes the smallest scales of the turbulence), it follows that with β , a dimensionless constant,

$$F(\varepsilon_T, \omega) = \beta \left(\frac{u_s^2}{\omega/\omega_s}\right)^2 \quad (57)$$

Also since $\varepsilon_T = u_0^3/\ell_0$, and experiment shows that the power spectral density continues smoothly from

its value in the inertial subrange into the energy-containing range, it is found that

$$\tilde{p}_s(\omega) \sim \left(\frac{u_0^2}{\omega/\omega_0}\right)^2 \quad (58)$$

and this same law applies for the total power spectral density. This result can be compared with that found by Meecham¹⁴⁶ for isotropic free turbulence where $\tilde{p}(\omega) \sim [u_0^2/(\omega/\omega_0)]^{7/2}$. When the acoustic power is measured in octave, one-third octave or any $(1/n)$ th octave bands, the above decay law becomes $(\omega/\omega_0)^{-1}$, a result of considerable importance in respect of measurements of airframe subjective noise in terms of perceived noise levels.

9.4 Noise from Aircraft Flying in "Clean" Configuration

Now, consider the special case of an aircraft flying at an altitude of H past a stationary observer on the ground. Here it is assumed that the aircraft is flying in its "clean" configuration at an aircraft lift coefficient of order $\overline{C}_L = 0.5$. By flying clean, it is meant that the aircraft is flying with wheels up and flaps and slats retracted. This flying configuration exists before the aircraft is approaching an airport at its approach speed where it flies in its high-lift or "dirty" configuration. The noise from this latter aircraft configuration is not considered here, since it goes beyond the scope of this chapter centered on that part of aeroacoustics devoted to jet and boundary layer noise. The flight speed is V_∞ . The wing mean chord is \bar{c} . We assume that over both the upper and lower surfaces the boundary layers are fully turbulent from the leading to the trailing edge and are attached. However, due to the adverse pressure gradient over the wing upper surface, corresponding to a given flight lift coefficient, the thickness of the upper surface boundary layer is considerably thicker than that over the under surface. The structure of the turbulent boundary layer is usually considered in coordinates fixed in the aircraft, and in this frame of reference it is easily demonstrated that the flow in the boundary layers evolves through a self-generating cycle, which convects the large-scale eddies in the outer boundary layer past the wing surface at a speed, V_c , slightly less than that of the freestream. The structure of the outer region of the boundary layer is governed by the entrainment of irrotational fluid from outside the boundary layer and its conversion to turbulence in crossing the superlayer, plus the diffusion of the small-scale erupting wall layer, containing a layer of longitudinal vortices, which were earlier attached to the wall. On leaving the trailing edge both the outer and inner regions combine and form the wake, which trails downstream of the trailing edge.

In the corresponding case of the aircraft in motion, the stationary observer, a distance H below the aircraft, sees the outer boundary layer of the aircraft wing and its wake moving very slowly, following the aircraft, at a speed, $V_\infty - V_c$. The merging of the wake

and the turbulent boundary layers becomes smeared and irregular. The wake decays slowly in time.

In Section 9.2 it was shown that the turbulence in the upper surface boundary layer, as it approaches the wing trailing edge, creates a pressure field that is amplified and scattered at distances close to the trailing edge, but small compared with the acoustic wavelength, corresponding to the frequency of the turbulence. It was shown that the scattered pressure field generates a strong diffracted sound field centered on the wing trailing edge, having an intensity per unit flow volume of

$$i(\mathbf{x}) \sim \frac{1}{2\pi^3} \frac{\rho_\infty \omega_0 u_0^4}{c_\infty^2 R^2} \left(\frac{\ell_0}{r_0} \right)^2 \sin \theta \cos^2 \left(\frac{\phi}{2} \right) \quad (59)$$

To find the sound intensity, or sound pressure level, at a ground observer, it is necessary to determine the fraction of the flow volume embracing the sound sources in the upper surface boundary layer that are within an acoustic wavelength of the wing trailing edge and which approach the trailing edge in their passage to form the wing's wake. First, it is noted that the upper surface boundary layer is almost at rest in the atmosphere following its formation by the moving aircraft. Indeed it is seen by the stationary observer as a layer of near stagnant air surrounding the aircraft and forming its wake. It is assumed that the mean chord of the wing, or control surface, is small compared with the height of the aircraft, so that the observer viewing the passage of the aircraft along any slant distance defined by (x, ϕ) directly below its flight trajectory, sees the trailing edge move a distance \bar{c} as the aircraft crosses the observer's line of sight. The total sound intensity, including the sound of all frequencies, received along the conical ray joining the aircraft to the observer, equals the sound emitted by sound sources within approximately a volume $V_e = \bar{c} \times b \times \delta$, where b is the wing span and δ is the upper surface boundary layer thickness at the wing trailing edge.* These sources emit from the near stagnant turbulent fluid as the trailing edge sweeps by, although the origin of the diffracted sound is moving with the trailing edge. Since the flight Mach numbers of interest are small, the Doppler effect on the frequency between the emitted sound and that received by the observer is neglected. The wind tunnel experiments of Brooks and Hodgson¹⁴⁷ on the trailing edge noise from an airfoil showed good agreement with the theoretical predictions.

The flight parameters of the aircraft, apart from its wing geometry, b, \bar{c} , and wing area, $S = b \times \bar{c}$, involve its vertical height, H , and slant height and angle (x, ϕ) , the flight speed V_∞ , and the Mach number with respect to the ambient speed of sound, M_∞ . The all-up weight

of the aircraft can be written $W = (\frac{1}{2})\rho_\infty V_\infty^2 \bar{C}_L S$, where \bar{C}_L is the aircraft lift coefficient. The total sound intensity in W/m^2 is given by

$$I(W/m^2) = \frac{1.7}{2\pi^3} \frac{\rho_\infty S V_\infty^3 M_\infty^2}{R^2} \left(\frac{u_0}{V_\infty} \right)^5 \left(\frac{\ell_0}{r_0} \right)^3 \times \left(\frac{\delta}{\ell_0} \right)_{TE} \cos^2 \left(\frac{\phi}{2} \right) \quad (60)$$

when $\theta = 90^\circ$; ℓ_0 is assumed equal to the upper surface boundary layer displacement thickness, based on experimental evidence relating to the peak frequency in the far-field noise spectrum. Hence,

$$I(W/m^2) = \frac{1.7}{\pi^3} \frac{W V_\infty M_\infty^2}{\bar{C}_L R^2} \left(\frac{u_0}{V_\infty} \right)^5 \left(\frac{\ell_0}{r_0} \right)^3 \times \left(\frac{\delta}{\ell_0} \right)_{TE} \cos^2 \left(\frac{\phi}{2} \right) \quad (61)$$

which is the value used for the lower bound estimates of the airframe noise component for an aircraft flying in the clean configuration at a $\bar{C}_L = 0.5$, as shown in Fig. 14 as well as for the hypothetical clean aircraft flying on the approach at a $\bar{C}_L = 2$, as shown in Fig. 15.

The interest in an aircraft flying in the clean configuration is that it provides a baseline value for the lowest possible noise for an aircraft flying straight and level of given weight and speed. Indeed, from flight tests, it has been demonstrated that the airframe noise component of all aircraft satisfies the simple V_∞^5

Figure 14 Lower bound for overall sound pressure level (OASPL) for clean pre-1980 aircraft flying at the approach \bar{C}_L ; aircraft height, $H = 120$ m and $\bar{C}_L = 0.5$. W = All-up weight, V = flight velocity, M = flight Mach number $= V/c_\infty$. (From Lockard and Lilley.¹⁴⁸)

*The true volume of sound sources may be somewhat less, but experiments confirm that all three quantities are involved in the determination of the sound intensity at ground level during an aircraft's flyover.

Figure 15 Lower bound for OASPL for clean post-1980 aircraft flying at the approach \bar{C}_L ; aircraft height, $H = 120$ m. $W =$ All-up weight, $V =$ flight velocity, $M =$ flight Mach number $= V/c_\infty$. (From Lockard and Lilley.¹⁴⁸)

relationship derived above. The clean configuration noise law applies also to gliders and birds, with the exception of the owl, which flies silently.[†] This demonstrates that the mechanism for airframe noise generation on all flying vehicles is the scattering of the boundary layer unsteady pressure field at the wing trailing edge and all control surfaces. In the clean configuration the aircraft is flying with wheels up, and trailing edge flaps and leading edge slats retracted. It is assumed that the aircraft lift coefficient, flying in this configuration, is of the order $\bar{C}_L = 0.5$.

An aircraft on its approach to landing has to fly at 1.3 times the stalling speed of the aircraft, and hence its lift coefficient has to be increased to about $\bar{C}_L = 2.0$. For a CTOL (conventional takeoff and landing) aircraft, such low speeds and high lift coefficients can only be achieved by lowering trailing edge flaps and opening leading edge slats. In addition, the undercarriage is lowered some distance from an airport to allow the pilot time to trim the aircraft for safe landing. The

aircraft is now flying in what is referred to as the dirty configuration. The undercarriage, flaps, and slats all introduce regions of highly separated turbulent flow around the aircraft and thus the airframe noise component of the aircraft noise is greatly increased. This noise is of the same order as the noise of the engine at its approach power. This is greater than the power required to fly the aircraft in its clean configuration due to the increase in drag of the aircraft flying in its dirty, or high-lift, configuration. Noise control of an aircraft is, therefore, directed toward noise reduction of both the engine and the high-lift configuration. The specified noise reduction imposes in addition the special requirement that this must be achieved at no loss of flight performance.

It is, therefore, important to establish not only a lower bound for the airframe noise component for the aircraft flying in its clean configuration, but also a lower bound for the airframe noise component when the aircraft is flying in its approach configuration. For this second lower bound, the assumption is made of a hypothetical aircraft that is able to fly at the required approach \bar{C}_L and speed for the aircraft at its required landing weight, with hush kits on its flaps and slats so that they introduce no extra noise to that of an essentially clean aircraft. For this second lower bound it is assumed the undercarriage is stowed. The approach of this hypothetical aircraft to an airport would therefore require that the undercarriage be lowered just before the airport was approached so that its increased noise would be mainly confined to within the airport and would not be heard in the residential communities further away from the airports boundary fence. The estimated increase in noise with increase in aircraft lift coefficient and consequent reduction in aircraft speed has been obtained by and Lockard and Lilley¹⁴⁸ from calculations of the increased boundary layer thickness at the wing trailing edge and the increase in the turbulent intensity as a result of the increased adverse pressure gradient over the upper surface of the wing.

9.5 Noise of Bluff Bodies

The aerodynamic noise generated by the turbulent wake arising from separated flow past bluff cylindrical bodies is of great practical importance. On aircraft it is typified by the noise from the landing gear with its assembly of cylinders in the form of its oleo strut, support braces, and wheels. From the Lighthill–Curle theory of aerodynamic noise it is shown that the fluctuations in aerodynamic forces on each cylindrical component can be represented as equivalent acoustical dipoles with a noise intensity proportional to V_∞^6 . No simple formula exists for landing gear noise, and reference should be made to Crighton¹³⁸. A procedure for estimating landing gear noise is given in the Aircraft Noise Prediction Program (ANOPP)¹⁴⁹. For detailed description of the complex flow around a circular cylinder, for a wide range of Reynolds numbers and Mach numbers, reference should be made to Zdravkovich.^{150,151}

[†]The almost silent flight of the owl through its millions of years of evolution is of considerable interest to aircraft designers since it establishes that strictly there is no lower limit to the noise that a flying vehicle can make. In the case of the owl, its feathers, different from those of all other birds, have been designed to eliminate scattering from the trailing edge so that its noise is proportional to V_∞^6 and not V_∞^5 . This amounts to a large noise reduction at its low flight speed. But the other remarkable feature of the owl's special feathers is that they eliminate sound of all frequencies above 2 kHz. Thus, the owl is able to approach and capture its prey, who are unaware of that approach, in spite of their sensitive hearing to all sounds above 2 kHz. This is the reason that we can claim that the owl is capable of silent flight.

9.6 The Noise Control of Aircraft

This is an important area of aeroacoustics which is considered in detail in later chapters of this handbook. But a few remarks on this important subject need to be made in this chapter dealing with aerodynamic noise and, in particular, jet noise and boundary layer noise. In all these subjects the noise generated from turbulent flows in motion has been shown to be a high power of the mean speed of the flow. Hence the most important step in seeking to reduce noise comes from flow speed reduction. But, in considering boundary layer noise, it has been shown that the mechanism for noise generation is the result of scattering of the boundary layer's pressure field at the trailing edge resulting in a sound power proportional to M_∞^5 . Thus, a prime method for noise reduction is to eliminate the trailing edge scattering, resulting in a sound power proportional to M_∞^6 . A number of methods have been proposed to achieve this noise reduction. These include trailing edge serrations or brushes and the addition of porosity of the surface close to the trailing edge.

PART II

FUNDAMENTALS OF VIBRATION

CHAPTER 11

GENERAL INTRODUCTION TO VIBRATION

Bjorn A. T. Petersson

**Institute of Fluid Mechanics and Engineering Acoustics
Technical University of Berlin
Berlin, Germany**

1 INTRODUCTION

An important class of dynamics concerns linear and angular motions of bodies that respond to applied disturbances in the presence of restoring forces. Examples are building structure response to an earthquake, unbalanced axle rotation, flow-induced vibrations of a car body, and the rattling of tree leaves. Owing to the importance of the subject for engineering practice, much effort has been and is still spent on developing useful analysis and predictive tools, some of which are detailed in subsequent chapters. Mechanical vibrations denote oscillations in a mechanical system. Such vibrations not only comprise the motion of a structure but also the associated forces resulting or applied. The vibration is characterized by its frequency or frequencies, amplitude, and phase. Although the time history of vibrations encountered in practice usually does not exhibit a regular pattern, the sinusoidal oscillation serves as a basic representation. The irregular vibration, then, can be decomposed in several frequency components, each of which has its own amplitude and phase.

2 BASIC CONCEPTS

It is customary to distinguish between deterministic and random vibrations. For a process of the former type, future events can be described from knowledge of the past. For a random process, future vibrations can only be probabilistically described. Another categorization is with respect to the stationarity of the vibration process. Hereby, a stationary process is featured by time-invariant properties (root mean square (rms) value, frequency range), whereas those properties vary with time in a nonstationary process.

Yet a third classification is the distinction between free and forced vibrations. In a free vibration there is no energy supplied to the vibrating system once the initial excitation is removed. An undamped system would continue to vibrate at its natural frequencies forever. If the system is damped, however, it continues to vibrate until all the energy is dissipated. In contrast, energy is continuously supplied to the system for a forced vibration. For a damped system undergoing forced vibrations the vibrations continue in a steady state after a transient phase because the energy supplied compensates for that dissipated. The forced vibration depends on the spectral form and spatial distribution of the excitation as well as on the dynamic characteristics of the system.

Finally, it is necessary to distinguish between linear and nonlinear vibrations. In this context, focus is on the former, although some of the origins of nonlinear processes will be mentioned. In a linear vibration, there is a linear relationship between, for example, an applied force and the resulting vibratory response. If the force is doubled, the response, hence, will be doubled. Also, if the force is harmonic of a single frequency, the response will be harmonic of the same frequency. This means that the principle of superposition is generally applicable for linear vibrations. No such general statements can be made for nonlinear vibrations since the features are strongly dependent on the kind of nonlinearity.

Encompassed in this section of the handbook is also the area of fatigue. It can be argued that the transition from linear to nonlinear vibration takes place just in the area of fatigue. Although short-time samples of the vibration appear linear or nearly linear, the long-term effects of very many oscillations are irreversible.

The analysis of an engineering problem usually involves the development of a physical model. For simple systems vibrating at low frequencies, it is often possible to represent truly continuous systems with discrete or lumped parameter models. The simplest model is the mass–spring–damper system, also termed the single-degree-of-freedom system since its motion can be described by means of one variable. For the simple mass–spring–damper system, exposed to a harmonic force excitation, thus, the motion of the mass will have the frequency of the force, but the amplitude will depend on the mass, spring stiffness, and damping. Also the phase of the motion, for example, relative that of the force, will depend on the properties of the system constituents. If, on the other hand, the simple system is exposed to random excitation, the motion of the mass cannot be described by its value at various time instances but is assessed in terms of mean values and variances or spectra and correlation functions. It is important to note that a random process is a mathematical model, not the reality. Finally, a sudden, nonperiodic excitation of the mass such as an impact or shock usually leads to a strong initial response with a gradual transition to free vibrations. Depending upon the severity of the shock, the response can be either linear or nonlinear. The motion of the mass–spring–damper system, therefore, includes both the frequencies of the shock and the natural frequency of the system. Accordingly, it is common to describe the motion in terms of a response spectrum, which depicts the maximum acceleration, velocity, or

displacement experienced by the simple system as a function of time, normalized with respect to the period of its natural vibration.

Common for all types of vibration is that the mass gives rise to an inertia force, the spring an elastic restoring force, and the damping acts as a converter of mechanical energy into some other form, most commonly heat. Additionally, an increase of the mass lowers the natural frequency, whereas an increase of the spring stiffness elevates it. The reduction of the natural frequency resulting from an increase of the damping can practically most often be neglected.

More complicated systems can be seen as composed of multiple mass–spring–damper systems termed multiple-degree-of-freedom systems. Such models like the simple mass–spring–damper system are usually only applicable for low frequencies.

As the frequency or the complexity of the system increases, it becomes necessary to consider the system as continuous, that is, the system parameters such as mass, stiffness, and damping are distributed. Simultaneously, analytical mathematical descriptions are usually substituted by numerical analysis methods such as finite element or boundary element methods. Alternatively, the vibrations can be described in terms of averages for the flow between and storage of energy in various parts of the complex system by means of statistical energy analysis.

The mechanical vibration process can be subdivided into four main stages as depicted in Fig. 1. The first stage—generation—comprises the origin of an oscillation, that is, the mechanism behind it. The second—transmission—covers the transfer of oscillatory energy from the mechanisms of generation to a (passive) structure. In the structure, be it the passive part of the source or an attached receiving structure, the third stage—propagation—is recognized whereby energy is distributed throughout this structural system. Fourth, any structural part vibrating in a fluid environment (air) will impart power to that fluid—radiation—that is perceived as audible sound.

This subdivision also serves as a basis for the activities in control of mechanical vibrations. Typical problems relating to generation are:

- Unbalances
- Misalignments
- Rolling over rough surfaces
- Parametric excitation
- Impacts
- Combustion

They are of great importance in noise control. Transmission entails problems such as:

- Shock and vibration isolation

Figure 1 Mechanical vibration as a process.

- Structural design (mismatch of structural dynamic characteristics)
- Machine monitoring and diagnosis

They are often the best compromise for noise and vibration control activities in view of cost and practicability. Prominent examples of problems belonging to propagation are:

- Ground vibrations
- Nondestructive testing
- Measurement of material properties
- Damping

Herein both wave theoretical approaches and modal synthesis can be employed. Finally, in the radiation phase are encountered problems like:

- Sound transmission
- Sound radiation

Most of the areas mentioned above will be treated in more detail in subsequent chapters.

3 BASIC RELATIONSHIPS AND VALIDITY

For small-scale mechanical vibrations, the process most often can be considered linear and the underlying equations are Newton's second law and Hooke's law. For lumped parameter systems consisting of masses m and massless springs of stiffnesses s , these laws read

$$m \frac{\partial^2 \xi_i}{\partial t^2} = F_i \quad i \in N \quad (1)$$

and

$$F_i = s \Delta \xi_i \quad i \in N \quad (2)$$

The two equations describe the inertia and elastic forces, respectively, required for the existence of elastic waves. The terms ξ_i are the displacement components of the masses; F_i denote the force components acting on the masses, and $\Delta \xi_i$ are the changes in lengths of the springs due to the forces F_i . Two approximations underlie Eqs. (1) and (2), the first of which is the replacement of the total derivative by the partial. This means that any convection is neglected and large amplitudes cannot be handled. The second approximation is that the spring is considered to behave linearly. The equations are frequently employed in Chapter 12 to derive the equations of motion for single- and multidegree-of-freedom systems.

For continuous systems, Eq. (1) and (2) have to be modified slightly. The masses must be replaced by a density ρ , the forces by stresses σ_{ij} , and the changes

in length are substituted by strains $\partial\xi/\partial x$. In such a way, the equations turn into^{1,2}

$$\rho \frac{\partial^2 \xi_i}{\partial t^2} = \frac{\partial \sigma_{ij}}{\partial x_j} + \beta_i \quad i, j \in [1, 2, 3] \quad (3)$$

$$\sigma_{ij} = G \left[\frac{2\mu}{1-2\mu} \left(\frac{\partial \xi_k}{\partial x_k} \right) \delta_{ij} + \left(\frac{\partial \xi_i}{\partial x_j} + \frac{\partial \xi_j}{\partial x_i} \right) \right] \quad i, j, k \in [1, 2, 3] \quad (4)$$

for the practically important case with a homogeneous, isotropic material of shear modulus G and Poisson's ratio μ . In Eqs. (3) and (4), use is made of the summation convention for tensors, that is, summation has to be made for repeated indices. The β_i are any body forces present. Alternatively, Eq. (4) can also be written in terms of the shear modulus G and Young's modulus E , which are related as $E = G(1 + 2\mu)$.

For a rod, subject to an axial force, for instance, the primary motion is, of course, in the axial direction, but there occurs also a contraction of the cross section. This contraction, expressed in terms of the axial strain amounts to $\varepsilon_2 = \varepsilon_3 = -\mu\varepsilon_1$.

The main difference between waves in fluids and elastic solids is that while only longitudinal or compressional waves exist in fluids in the absence of losses, also shear waves occur in solids. In the one-dimensional case, compressional waves are governed by the wave equation

$$\left(\frac{d^2}{dx_1^2} - k_C^2 \right) \xi_1 = F'(x_1) \quad (5)$$

whereas shear waves, with the displacement in direction 3, perpendicular to the propagation direction 1, obey

$$\left(\frac{d^2}{dx_1^2} - k_S^2 \right) \xi_3 = T'(x_1) \quad (6)$$

for harmonic processes. In Eqs. (5) and (6), $k_C^2 = \omega^2 \rho / E$ and $k_S^2 = \omega^2 \rho / G$ are the wavenumbers of the compressional and shear waves, respectively, where $\omega = 2\pi f$ is the angular frequency. F' and T' are the axial and transverse force distributions, respectively. Other wave types such as bending, torsion, and Rayleigh waves can be interpreted as combinations of compressional and shear waves.

Owing to its great practical importance with respect to noise, however, the bending wave equation is given explicitly for the case of a thin, isotropic, and homogeneous plate:

$$(\nabla^4 - k_B^4) \xi_3 = \frac{12(1-\mu^2)}{Eh^3} \sigma_e \quad (7)$$

Herein, $k_B^4 = 12(1-\mu^2)\rho\omega^2/(Eh^2)$ is the bending wavenumber, where h is the plate thickness. ξ_3 is

the displacement normal to the plate surface and σ_e is the externally applied force distribution. This wave equation, which is based on Kirchhoff's plate theory, can normally be taken as valid for frequencies where the bending wavelength is larger than six times the plate thickness.

The equation is also applicable for slender beams vibrating in bending. The only modifications necessary for a beam of rectangular cross section are the removal of the factor $1-\mu^2$ in Eq. (7) as well as in the bending wavenumber and insertion of the beam width b in the denominator of the right-hand side. Also, the force distribution changes to a force per unit length σ'_e .

Linear mechanical vibrations are often conveniently described in exponential form:

$$\xi(t) = \text{Re}[Ae^{j\omega t}] \quad (8)$$

where A is an amplitude, which is complex in general, that is, it has a phase shift relative to some reference. This enables the description of vibrations in terms of spectra, which means that the time dependence is written as a sum or integral of terms in the form of Eq. (8), all with different amplitudes, phases, and frequencies.

For the assessment of, for instance, the merit of design or vibration control measures, there is a growing consensus that this should be undertaken with energy- or power-based quantities. Hereby, nonstationary processes such as vibrations resulting from impacts encompassing a finite amount of energy are assessed by means of

$$\begin{aligned} E &= \int_0^{T_p} F(t) \xi(t) dt = \int_0^{T_p} \text{Re}[\hat{F}e^{j\omega t}] \text{Re}[\hat{\xi}e^{j\omega t}] dt \\ &= \frac{1}{2} \text{Re}[\hat{F}\hat{\xi}^*] \end{aligned} \quad (9)$$

while those that can be considered stationary, such as, for example, the fuselage vibration of a cruising aircraft, are appropriately assessed by means of the power averaged over time:

$$\begin{aligned} \overline{W} &= \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T F(t) \frac{\partial \xi(t)}{\partial t} dt \\ &= \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T \text{Re}[\hat{F}e^{j\omega t}] \text{Re}[\hat{\xi}e^{j\omega t}] dt \\ &= \frac{1}{2} \text{Re}[\hat{F}\hat{\xi}^*] \end{aligned} \quad (10)$$

In the two expressions above, the two latter forms apply to harmonic processes. Moreover, the vector nature of force, displacement, and velocity is

herein suppressed such that collinear components are assumed. The advantage of using energy or power is seen in the fact that the transmission process involves both kinematic (motion) and dynamic (force) quantities. Hence, observation of one type only can lead to false interpretations. Furthermore, the use of energy or power circumvents the dimensional incompatibility of the different kinematic as well as dynamic field variables. The disadvantages lie mainly in the general need of a phase, complicating the analysis as well as the measurements.

As mentioned previously, the vibration energy in a system undergoing free vibrations would remain constant in the absence of damping. One consequence of this would be that the vibration history of the system would never fade. Since such behavior contradicts our experience, the basic equations have to be augmented to account for the effect of the inevitable energy losses in physical systems. The conventional way to account for linear damping is to modify the force–displacement or stress–strain relations in Eq. (2) or (4). The simplest damping model is a viscous force, proportional to velocity, whereby Eq. (2) becomes

$$F = s \Delta \xi + C \frac{\partial}{\partial t} (\Delta \xi) \quad (11)$$

in which C is the damping constant. For continua, a similar viscous term has to be added to Eq. (4). This expression appropriately describes dampers situated in parallel with the springs but do not correctly describe the behavior of materials with inner dissipative losses. Other models with a better performance, provided the parameters are chosen properly, can be found in Zener.³ One such is the Boltzmann model, which can be represented by

$$F(t) = s_0 \Delta \xi(t) - \int_0^\infty \Delta \xi(t - \tau) \varphi(\tau) d\tau \quad (12)$$

In this expression, $\varphi(\tau)$ is the so-called relaxation function, consisting of a sum of terms in the form $(D/\tau_R) \exp(-\tau/\tau_R)$ where D is a constant and τ_R the relaxation time. The relaxation time spans a wide range, from 10^{-9} up to 10^5 seconds. The model represents a material that has memory such that the instantaneous value of the viscous force $F(t)$ not only depends on the instantaneous value of the elongation $\Delta \xi(t)$ but also on the previous history $\Delta \xi(t - \tau)$.

Additional loss mechanisms are dry or Coulomb friction at interfaces and junctions between two structural elements and radiation damping, caused by waves transmitted to an ambient medium. Here, it should be noted that while the latter can be taken as a linear phenomenon in most cases of practical interest, the former is a nonlinear process.

Although Eq. (12) preserves linearity because no product or powers of the field quantities appear, it yields lengthy and intractable expressions when employed in the derivation of the equations of

motion. In vibroacoustics, therefore, this is commonly circumvented by introducing complex elastic moduli for harmonic motion⁴

$$E = E_0(1 + j\eta) \quad G = G_0(1 + j\eta) \quad (13)$$

where E_0 and G_0 are the ordinary (static) Young's and shear moduli, respectively. The damping is accounted for through the loss factor $\eta = E_{\text{diss}}/(2\pi E_{\text{rev}})$, that is, the ratio of the dissipated-to-reversible energy within one period. In many applications, the loss factor can be taken as frequency independent. The advantage of this formalism is that loss mechanisms are accounted for simply by substituting the complex moduli for the real-valued ones everywhere in the equations of motion. It must be observed, however, that complex moduli are mathematical constructs, which are essentially applicable for harmonic motion or superimposed harmonic motions. Problematic, therefore, is often a transformation from the frequency domain to that of time when assumed or coarsely estimated loss factors are used.

The relations described above can be used to develop the equations of motion of structural systems. With the appropriate boundary and initial conditions, the set of equations can be used in many practical applications. There remain, however, situations where their application is questionable or incorrect and the results can become misleading. Most often, this is in conjunction with nonlinear effects or when parameters vary with time. Some important causes of nonlinearities are:

- Material nonlinearities, that is, the properties s , E , G , and C are amplitude dependent as can be the case for very large scale vibrations or strong shocks.
- Frictional forces that increase strongly with amplitude, an effect that is often utilized for shock absorbers.
- Geometric nonlinearities, which occur when a linear relationship no longer approximates the dynamic behavior of the vibrating structure. Examples of this kind of nonlinearity are when the elongation of a spring and the displacement of attached bodies are not linearly related, Hertzian contact with the contact area changing with the displacement,⁵ and large amplitude vibrations of thin plates and slender beams such that the length variations of the neutral layer cannot be neglected.⁶
- Boundary constraints, which cannot be expressed by linear equations such as, for example, Coulomb friction or motion with clearances.⁷
- Convective forces that are neglected in the inertia terms in Eqs. (1) and (3).

Slight nonlinearities give rise to harmonics in the response that are not contained in the excitation. For strong nonlinearities, a chaotic behavior may occur.

Examples of parametric changes in time or space are:

- Changes in a pendulum length.
- Stiffness changes due to variations of the point of contact, for example, a tooth in a gear wheel is considered as a short cantilever beam, for which the forcing point is continuously moving.
- Impedance variations as experienced by a body moving on a spatially varying supporting system such as a wheel on a periodically supported rail.

4 ENERGY-BASED PRINCIPLES

An alternative approach for developing the equations of motion for a vibrating system is established via the energies. The most powerful method of this kind is based on Hamilton's principle:

$$\int_{t_1}^{t_2} [\delta(E_{\text{kin}} - E_{\text{pot}}) + \delta V] dt \quad (14)$$

which states that “for an actual motion of the system, under influence of the conservative forces, when it is started according to any reasonable initial conditions, the system will move so that the time average of the difference between kinetic and potential energies will be a minimum (or in a few cases a maximum).”⁸ In Eq. (14), E_{kin} and E_{pot} denote the total kinetic and potential energies of the system and the symbol δ indicates that a variation has to be made. For dissipative systems, either the variation in Eq. (14) is augmented by a dissipation function involving quadratic expressions of relative velocities^{9,10} or the loss factor is simply introduced. External excitation or sinks can be incorporated by also including the virtual work done δV . Accordingly, all kinds of linear, forced vibrations can be handled. Hamilton's principle is highly useful in vibroacoustics. It can be seen as the starting point for the finite element method,^{10,11} be used for calculating the vibrations of fluid loaded as well as coupled systems,¹² and to determine the phase speed of different wave types.^{13–15}

A special solution to Eq. (14) is $\overline{E_{\text{kin}}} = \overline{E_{\text{pot}}}$ where the overbar, as before, denotes time average. This special solution is known as Rayleigh's principle,¹⁵ which states that the time averages of the kinetic and potential energies are equal at resonance. Since

$$\overline{E_{\text{kin}}} \propto \overline{\left(\frac{\partial \xi_i}{\partial t}\right)^2} \propto \omega^2 \overline{\xi_i^2}$$

the principle realizes a simple method to estimate resonance frequencies using assumed spatial distributions of the displacements, required for establishing the energies. Hereby, it should be noted that provided the boundary conditions can be satisfied, a first-order error

in the assumed distribution only results in a second-order one in the frequencies. In any case, Rayleigh's principle always renders an upper bound for the resonance frequency. An extension of this principle is the so-called Rayleigh–Ritz method, which can be applied to assess higher resonance frequencies as well as mode shapes.^{14,15} In Mead,¹⁶ Rayleigh's principle is employed to calculate the first pass- and stop-bands of periodic systems.

With respect to calculations of resonance frequencies, mode shapes, impulse or frequency responses, and the like for multidegree-of-freedom systems, Lagrange's equations of the second type

$$\frac{d}{dt} \left\{ \frac{\partial(E_{\text{kin}} - E_{\text{pot}})}{\partial \dot{\xi}_n} - \frac{\partial(E_{\text{kin}} - E_{\text{pot}})}{\partial \xi_n} \right\} = 0 \quad (15)$$

constitute a practical means. In these equations, $\dot{\xi}_n$ and ξ_n are the n th velocity and displacement coordinates, respectively. In cases with external excitation F_n , the forces have to be included in the right-hand side.

Most differential equations describing linear mechanical vibrations are symmetric or self-adjoint. This means that the reciprocity principle is valid.¹⁷ The principle is illustrated in Fig. 2 in which a beam is excited by a force F_A at a position A and the response ξ_B is observed at the position B in a first realization. In the second, reciprocal realization, the beam is excited at position B and the response is observed at A . The reciprocity now states that

$$F_A \xi'_A = F'_B \xi_B \Leftrightarrow \frac{F_A}{\xi_B} = \frac{F'_B}{\xi'_A} \quad (16)$$

which means that excitation and response positions can be interchanged as long as the directions of F_A and ξ'_A as well as F'_B and ξ_B are retained. The principle is also valid for other pairs of field variables, provided their product results in an energy or power quantity such as, for example, rotations and moments. An extension of the reciprocity principle, invoking the superposition principle, is termed the law of mutual energies.¹⁸

The reciprocity of linear systems has proven a most useful property in both theoretical and experimental work.^{19–21} If, for example, F_A is cumbersome to compute directly or position A is inaccessible in

Figure 2 Illustration of reciprocity.

a measurement, the reciprocal realization can be employed to indirectly determine the force sought.

5 DESCRIPTIONS OF VIBRATIONS

As mentioned previously, mechanical vibrations are commonly represented in the frequency domain by means of spectral functions. The functions are usually ratios of two complex variables having the same time dependence, for example, $e^{j\omega t}$. The most common spectral functions are frequency response functions and transfer functions. Typical examples of the former kind are defined as:

- Input mobility

$$Y_{\xi F}(x_S|x_S) = \dot{\xi}(x_S)/F(x_S)$$

$$Y_{\dot{\theta} M}(x_S|x_S) = \dot{\theta}(x_S)/M(x_S)$$

- Transfer mobility

$$Y_{\xi F}(x_R|x_S) = \dot{\xi}(x_R)/F(x_S)$$

$$Y_{\dot{\theta} M}(x_R|x_S) = \dot{\theta}(x_R)/M(x_S)$$

- Cross-transfer mobility

$$Y_{\dot{\theta} F}(x_R|x_S) = \dot{\theta}(x_R)/F(x_S)$$

$$Y_{\xi M}(x_R|x_S) = \dot{\xi}(x_R)/M(x_S)$$

In these expressions, $\dot{\xi}$ is the velocity in the direction of the force F whereas $\dot{\theta}$ is the rotational velocity directed as the moment M ; x_S and x_R are the positions of the excitation and some observation point, removed from the excitation, respectively. The mobility thus represents the response of a structure due to a unit excitation. In the literature, other forms of frequency response functions are also found, such as receptance ($R = \xi/F$), acceleration ($A = \dot{\xi}/F$), and mechanical impedance ($Z = F/\dot{\xi}$). A significant advantage of frequency response functions is that they can be used to predict the response of structures to arbitrary excitations in practical applications. The input mobility is particularly important since it is intimately associated with the power, for example,

$$W = \frac{1}{2} \text{Re}[Y_{\xi F}] |F|^2 \quad W = \frac{1}{2} \text{Re}[Y_{\dot{\theta} M}] |M|^2 \quad (17)$$

which describe the power transmitted to a structure by a point force and moment excitation, respectively.

Transfer functions, on the other hand, are normally ratios between two observations of the same field variable, such as, for instance, $H_{12} = \xi(x_1)/\xi(x_2)$, where the displacement at position x_1 is compared with that at x_2 . Both kinds of spectral functions are today conveniently measured by means of multichannel signal analysers; see Chapter 40.

A representation of the vibrating system in the time domain can be achieved by means of the impulse response function or Green's function g . This time-dependent function is the solution to the equation

$$\left(\frac{\partial^2}{\partial x^2} - \frac{1}{c_L^2} \frac{\partial^2}{\partial t^2} \right) g(x, t|x_S, t_0) = \delta(x - x_S) \delta(t - t_0) \quad (18)$$

in the one-dimensional case and represents the vibrational response at a position x and a time instant t due to a unit impulse, described by Dirac's delta function δ , at a position x_S at time t_0 . Similar impulse response function can be defined for two- and three-dimensional systems as well as coupled systems by substituting the adequate set of differential equations for that within parenthesis on the left-hand side. The impulse response function can be said to be a solution to the equation of motion for a special excitation. A set of impulse response functions for various positions, thus, can give all the information required about the vibrating system.

This approach has the advantage in transient analyses that the response to an arbitrary excitation is obtained directly from the convolution integral:

$$\xi(x, t) = \int F'(x_S, t_0) g(x, t|x_S, t_0) dx_S dt_0 \quad (19)$$

In this form, the vibration response is expressed as a sum of many very short and concentrated impulses. Owing to this, impulse response functions are often used for numerical computations of response time histories such as those due to shocks, but they are also suitable when nonlinear devices are attached or applied to linearly vibrating systems.²²

There is a strong relationship between the impulse response function and the frequency response function in that the Fourier transform of either yields the other, save some constant. This relationship is often used to develop the impulse response function.

As an alternative to the wave theoretical treatment of vibrations dealt with above, a modal description of the vibrations can be employed for finite structures. As mentioned previously, a finite system responds at preferred frequencies, the natural frequencies or eigenfrequencies ω_n , when exposed to a short, initial disturbance. Associated with those eigenfrequencies are preferred vibrational patterns, the natural vibrations or eigenfunctions $\phi_n(x)$. The modal description draws upon the fact that the vibrations can be expressed as a sum of eigenfunctions or (normal) modes.²³ In a one-dimensional case this means that

$$\xi(x) = \sum_{n=1}^{\infty} \hat{\xi}_n \phi_n(x) \quad (20)$$

where ξ is the displacement but can, of course, be any other field variable. $\hat{\xi}_n$ are the modal amplitudes. The eigenfunctions are the solutions to the homogeneous

equation of motion and have to satisfy the boundary conditions. By employing this representation, it is possible to express forced vibration through the modal expansion theorem:

$$\xi(x) = \sum_{n=1}^{\infty} \frac{\phi_n(x)}{\Lambda_n[\omega_n^2(1 + j\eta_n) - \omega^2]} \times \int_L F'(x)\phi_n(x) dx \quad (21)$$

where $\Lambda_n = \int_L m'(x)\phi_n^2(x) dx$ is the so-called norm and $F'(x)$ is a harmonic force distribution. The damping of the system is accounted for through the modal loss factors η_n , which have to be small. The theorem states that the response of a system to some excitation can be expressed in terms of the eigenfunctions and the eigenfrequencies of the system.²⁴ A sufficient condition for the validity is that the system is “closed,” that is, no energy is leaving it. Otherwise, the orthogonality of the eigenfunctions must be verified. Such modal expansions are practically useful mainly for problems involving low or intermediate frequencies since the number of modes grows rapidly with frequency in the general case. For high frequencies, the modal summation in Eq. (21) can be approximated by an integral and a transition made to spatially averaged descriptions of the vibration.

Equation (21) can also be used for free vibrations in the time domain, for example, for response calculations from short pulses or shocks. The corresponding expression, obtained by means of a Fourier transform, can be written as²⁴

$$\xi(x, t) = \sum_{n=1}^{\infty} \frac{I_n}{\omega_n} \phi_n(x) e^{-j\eta_n \omega_n t/2} \cos \omega_n t \quad t > 0 \quad (22)$$

wherein I_n are functions of the excitation and its position. The expression shows that the free vibration is composed of decaying modes where the number of significant modes is strongly dependent on the duration of the exciting pulse. For short impulses, the number of significant modes is generally quite substantial, whereas only the first few might suffice for longer pulses such as shocks.

When the number of modes in a frequency band (modal density) gets sufficiently large, it is often more appropriate and convenient to consider an energetic description of the vibration. The primary aim is then to estimate the distribution of energy throughout the vibrating system. The energy is taken to be the long-term averaged sum of kinetic and potential energy, from which the practically relevant field variables can be assessed. Such a description with spatially averaged energies is also justified from the viewpoint that there is always a variation in the vibration characteristics of nominally equal systems such that a fully deterministic description becomes less meaningful. The uncertainty

of deterministic predictions, moreover, increases with system complexity and is also related to wavelength, that is, to the frequency since small geometrical deviations from a nominal design have a stronger influence as their dimensions approach the wavelength. As in room acoustics, therefore, statistical formulations such as statistical energy analysis (SEA)²⁵ are widely employed in mechanical vibrations where subsystems are assumed drawn from a population of similar specimens but with random parameters.

The energy imparted to a structure leads to flows of energy between the subsystems, which can be obtained from a power balance whereby also the losses are taken into account. This is most simply illustrated for two coupled subsystems, as depicted in Fig. 3 where power is injected in subsystem 1 W_{1in} . This is partially transmitted to subsystem 2 W_{21} and partially dissipated W_{1diss} . Similarly, the power transmitted to subsystem 2 is partially retransmitted to subsystem 1 W_{12} and partially dissipated W_{2diss} . This means that the power balance for the system can be written as

$$\begin{aligned} W_{1in} + W_{12} &= W_{21} + W_{1diss} \\ W_{21} &= W_{12} + W_{2diss} \end{aligned} \quad (23)$$

For linear subsystems, the power transmitted between them is proportional to the energy of the emitting subsystem and, hence, to the average mean square velocity, where the equality of kinetic and potential energies for resonantly vibrating systems is invoked. A spatial average is denoted by $\langle \rangle$ enclosing the variable. Accordingly, the energy flows can formally be written as

$$W_{21} = C_{21} \langle |\dot{\xi}_1|^2 \rangle \quad W_{12} = C_{12} \langle |\dot{\xi}_2|^2 \rangle \quad (24)$$

where C_{21} and C_{12} are coefficients that are dependent on the spatial and temporal coupling of the two vibration fields. The main advantages of SEA are the “analysis philosophy,” transparency of the approach and that it swiftly can furnish results, which give good guidance to important parameters, also for rather

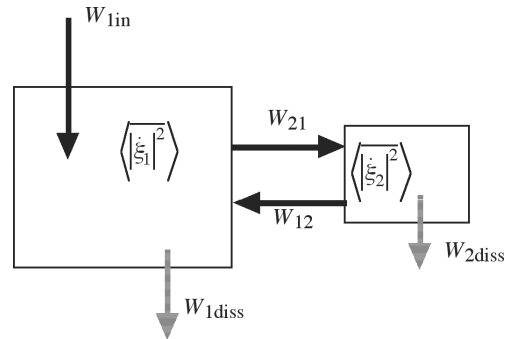

Figure 3 Energy flows in two coupled subsystems.

Table 1 Material Properties

Material	ρ (kg/m ³)	E (GPa)	G (GPa)	μ —	c_C (m/s)	c_S (m/s)

Moscow, Russia

1 INTRODUCTION

Both free and forced vibration models of simple linear discrete and continuous vibratory mechanical systems are widely used in analyzing vibrating engineering structures. In discrete systems (also called lumped-parameter systems), the spatial variation of the deflection from the equilibrium position is fully characterized by a finite number of different amplitudes. In continuous systems (or distributed parameter systems), the deflection amplitude is defined by a continuous function of the spatial coordinates. Mathematically, the difference between the two types of vibratory systems is that vibrations of discrete systems are described by ordinary differential equations, while vibrations of continuous systems are described by partial differential equations, which are much more difficult to solve. Physically, the difference means that, in discrete systems, the most simple (elementary) motion is sinusoidal in time oscillation of inertia elements, while in continuous systems the elementary motion is wave motion that can travel along the system. In engineering practice, continuous systems are often replaced, for example, using the finite element method, by discrete systems.

1.1 Single-Degree-of-Freedom System

A system with single degree of freedom (SDOF system) is the simplest among the vibratory systems. It consists of three elements: inertia element, elastic element, and damping element. Its dynamic state is fully described by one variable that characterizes deflection of the inertia element from the equilibrium position. For illustration, some SDOF systems are presented in Table 1, where indicated they are all three elements and the corresponding variable.

The role of SDOF systems in vibration theory is very important because any linear vibratory system behaves like an SDOF system near an isolated natural frequency and as a connection of SDOF systems in a wider frequency range.¹

It is commonly accepted to represent a general SDOF system as the mass–spring–dashpot system shown in Table 1 as number one. Therefore, all the results are presented below for this SDOF system. To apply the results to physically different SDOF systems, the parameters m , k , c , and the displacement x should be replaced by the corresponding quantities as done in

Table 1. Usually, the inertia and elastic parameters are identified from the physical consideration, while the damping coefficient is estimated from measurement.

The ordinary differential equation that describes vibration of the mass–spring–dashpot system is obtained from Newton's second law and has the form

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = f(t) \quad (1.1)$$

where $x(t)$ is the displacement of the mass from the equilibrium position, and $f(t)$ is an external force applied to the mass. The three terms in the left-hand side of the equation represent the force of inertia, dashpot reaction force, and the force with which the spring acts on the mass.

1.2 Free Vibration

Free or unforced vibration of the SDOF system corresponds to zero external loading, $f(t) = 0$; it is described by solutions of homogeneous Eq. (1.1) and uniquely determined by the initial conditions. If $x_0 = x(0)$ and $\dot{x}_0 = \dot{x}(0)$ are the displacement and velocity at the initial moment $t = 0$, the general solution for free vibration at time $t > 0$ is

$$x(t) = x_0 e^{-\zeta\omega_0 t} \cos \omega_d t + \frac{\dot{x}_0 + \zeta\omega_0 x_0}{\omega_d} e^{-\zeta\omega_0 t} \sin \omega_d t \quad (1.2)$$

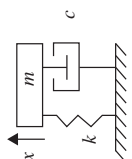

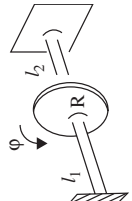

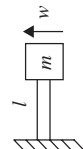

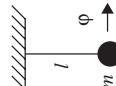

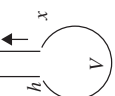

Here ζ is the *damping ratio*, ω_0 is the *undamped natural frequency*, and ω_d is the natural frequency of the damped system:

$$\omega_0 = \sqrt{k/m} \quad \zeta = c/2m\omega_0 \quad \omega_d = \omega_0 \sqrt{1 - \zeta^2} \quad (1.3)$$

Further, it is assumed that the amount of damping is not very large, so that $1 > \zeta$ and the natural frequency ω_d is real valued. (When damping is equal to or greater than the critical value, $\zeta \geq 1$ or $c^2 \geq 4mk$, the system is called overdamped and its motion is aperiodic.)

The time history of the vibration process (1.2) is shown in Fig. 1. It is seen from Eq. (1.2) and Fig. 1 that the free vibration of a SDOF system, that is its response function to any initial excitation x_0 and \dot{x}_0 , is always harmonic oscillation with natural frequency ω_d and exponentially decaying amplitude. The rate of decay is characterized by the damping ratio ζ . Sometime, instead of ζ , other characteristics of decay

Table 1 Examples of SDOF System

Vibratory System		Inertia Element	Elastic Element	Damping Element	Variable
	Mass-spring-dashpot system	Mass, m (kg)	Spring with stiffness k (N m ⁻¹)	Dashpot with damping coefficient c (kg s ⁻¹)	Linear displacement x (m)
		Moment of the disc inertia $\frac{mR^2}{2}$ (kg m ²)	Static torsional stiffness of the shaft $G \frac{\pi a^4}{2} \left(\frac{1}{l_1} + \frac{1}{l_2} \right)$ (N m) G = shear modulus a = radius of the shaft	Losses in shaft material	Angular displacement of the disc φ (rad)
	Cantilever beam with a mass at the end	Mass, m (kg)	Static flexural stiffness of the beam $\frac{3EI}{l^3}$ (N m ⁻¹) E = Young's modulus I = moment of inertia	Losses in beam material	Linear displacement of the mass w (m)
		Moment of inertia ml^2 (kg m ²)	Angular stiffness due to gravity $g = 9.8$ (m s ⁻²) mg/l (N m)	Friction in suspension axis	Angular displacement φ (rad)
	Helmholtz resonator (long-necked open vessel)	Mass of the fluid in the neck ρSh (kg) ρ = density S = cross-sectional area	Static stiffness of the fluid in the vessel $\frac{p_0 S^2}{V}$ (N m ⁻¹) p_0 = atmospheric pressure V = vessel volume	Viscous losses at the neck walls and radiation losses	Linear displacement of the fluid in the neck x (m)

Figure 1 Free vibration of a mass–spring–dashpot system with initial conditions:

$$x_0 = 10^{-3} \text{ m}; \dot{x}_0 = 0 \text{ (solid line),}$$

$$x_0 = 0; \dot{x}_0 = 0.2 \text{ ms}^{-1} \text{ (dashed line).}$$

are introduced. These are the logarithmic decrement and loss factor η —see Section 1.4 and Chapter 15.

1.3 Forced Harmonic Vibration

If, beside the initial condition, an SDOF system is acted upon by external force $f(t)$, its motion is the superposition of two components: free vibration (1.2)

and the vibration caused by $f(t)$ and called forced vibration. In the simplest case the force is harmonically varying in time and represented, for the sake of convenience, in the complex form as

$$f(t) = \text{Re}(f e^{-i\omega t}) \quad (1.4)$$

where ω is an arbitrary frequency and f is the complex amplitude (details of the complex representation see in Chapter 11); the forced component of the system response is also a harmonic function of the same frequency ω . When represented in the similar complex form, this component is characterized by the complex-valued displacement amplitude x , which is equal to

$$x = f/k(\omega) \quad k(\omega) = k - m\omega^2 - i\omega c$$

$$= k[e(1 - \varepsilon^2) - i\eta_0\varepsilon] \quad (1.5)$$

where $\varepsilon = \omega/\omega_0$, $k(\omega)$ is the complex-valued *dynamic stiffness* of the system, η_0 being the resonance value of the loss factor given by

$$\eta_0 = \frac{c}{m\omega_0} = 2\zeta \quad (1.6)$$

Figure 2 presents the absolute value and phase of the displacement amplitude (1.5) of the SDOF–system for different rates of damping. The curves in Fig. 2a are

Figure 2 (a) Displacement amplitude normalized with the static displacement $x_s = f/k$ and (b) phase vs. dimensionless frequency ω/ω_0 for different values of the resonant loss factor $\eta_0 = 0; 0.03; 0.1; 0.3$.

commonly referred to as the *frequency response functions*, or FRFs. It is seen from Fig. 2 that the displacement FRF is maximum at frequency $\omega_0\sqrt{1-\eta_0^2}/2$. The phenomenon when a system response has maximum values is called *resonance*. Resonance is also observed in the velocity and acceleration responses of the SDOF system. However, they reach maximum values at different frequencies. The resonance frequency of the velocity response is equal to the undamped natural frequency ω_0 , the acceleration amplitude reaches its maximum value at frequency $\omega_0/\sqrt{1-\eta_0^2}/2$, while none of the physical variables resonates at the damped natural frequency $\omega_d = \omega_0\sqrt{1-\eta_0^2}/4$. Note that for small damping, all these frequencies are about equal. The amplitude of the system response at the resonance frequency is inversely proportional to the loss factor η_0 .

In an SDOF system, one can also observe *antiresonance*—the phenomenon when the system response is minimum. Consider the case of an external force that is applied to the spring–dashpot connection point while the mass is free from an external loading, as shown in Fig. 3. Figure 4 presents the amplitude and phase of the velocity response at the driving point normalized with $f/m\omega_0$ as a function of frequency for various rates of damping. The antiresonance frequency is very close to undamped natural frequency ω_0 (although not exactly equal). At this frequency, the velocity amplitude at the driving point is minimum while the amplitude of the mass velocity is maximum.

The displacement and acceleration at the driving point also manifest antiresonance. However, their

Figure 3 SDOF system with an external force applied to the spring–dashpot connection point.

antiresonance frequencies slightly differ from that of the velocity response—higher for the displacement and lower for the acceleration, the difference being proportional to η_0^2 . The amplitude of the response at the antiresonance frequency is proportional to the loss factor η_0 .

From analysis of Figs. 2 and 4 one can conclude that the phenomena of resonance and antiresonance observed in forced vibration are closely related to free

Figure 4 Driving point (a) velocity amplitude normalized with $v_n = f/m\omega_0$ and (b) phase vs. frequency ω/ω_0 for different values of loss factor $\eta_0 = 0; 0.03; 0.1; 0.3$.

vibration of the SDOF system at its natural frequency. Their occurrence depends on the point the external force is applied to and on what kind of response is considered. These two phenomena are likely the main features of the frequency response functions of all known linear vibratory systems.

1.4 Energy Characteristics

For an SDOF system executing harmonic vibration under the action of external force (1.4), applied to the mass, the time-average kinetic energy T , potential energy U , and the power Φ dissipated in the dashpot are equal to

$$\begin{aligned} T &= \frac{1}{4} m |\dot{x}|^2 = \frac{|f|^2}{4k} \frac{\varepsilon^2}{(1 - \varepsilon^2)^2 + \eta_0^2 \varepsilon^2} \\ U &= \frac{1}{4} k |x|^2 = \frac{|f|^2}{4k} \frac{1}{(1 - \varepsilon^2)^2 + \eta_0^2 \varepsilon^2} \\ \Phi &= \frac{1}{2} c |\dot{x}|^2 = \frac{|f|^2}{2m\omega_0} \frac{\eta_0 \varepsilon^2}{(1 - \varepsilon^2)^2 + \eta_0^2 \varepsilon^2} \end{aligned} \quad (1.7)$$

where $\varepsilon = \omega/\omega_0$. At low frequencies ($\omega < \omega_0$) the potential energy is greater than the kinetic energy. At high frequencies ($\omega > \omega_0$), on the contrary, the kinetic energy dominates. The only frequency where they are equal to each other is the natural undamped frequency ω_0 .

The *loss factor* $\eta(\omega)$ of the system is defined at frequency ω as the ratio of the vibration energy dissipated in the dashpot during one period $T = 2\pi/\omega$ to the time average total energy $E = T + U$ of the system:

$$\eta(\omega) = \frac{\Phi}{\omega E} = \eta_0 \frac{2\varepsilon}{1 + \varepsilon^2} \quad (1.8)$$

where η_0 is the maximum value (1.6) of the loss factor.

The graph of the loss factor as a function of frequency is shown in Fig. 5. It is seen from the figure that the loss factor is small at low and high frequencies. It reaches the maximum value at the undamped natural frequency ω_0 .

Direct measurement of the dissipated power (1.7) and loss factor (1.8) is practically impossible. However, there are some indirect methods for obtaining $\eta(\omega)$, one of which is the following. When an external harmonic force (1.4) acts on the system, one can measure, for example, with the help of an impedance head, the complex amplitude f of the force and the complex velocity amplitude \dot{x} at the driving point, and compute the complex power flow into the system:

$$P = \frac{1}{2} \dot{x}^* f = I + iQ. \quad (1.9)$$

where the asterisk denotes the complex conjugate. The real part of P , called *the active power flow*, is the time-average vibration power injected into the system by the external source. Due to the energy conservation law,

Figure 5 The loss factor, Eq. (1.8), normalized with the resonance value $\eta_0 = c/m\omega_0$ vs. dimensionless frequency ω/ω_0 .

this power should be equal to the power dissipated in the system so that the equality takes place:

$$I = \Phi \quad (1.10)$$

If, using the measured velocity amplitude \dot{x} , one can compute the total energy of the system E , one also can obtain the loss factor (1.8).

The imaginary part Q of the complex power flow (1.9), called *the reactive power flow*, does not relate to dissipation of energy. It satisfies the equation

$$Q = 2\omega(U - T) \quad (1.11)$$

and may be regarded as a measure of closeness of the system vibration to resonance or antiresonance. Note that Eqs. (1.10) and (1.11) hold for any linear vibratory system.

Another indirect method of measuring the loss factor (more exactly its resonance value η_0) is based on analysis of the velocity FRF. If ω_1 and ω_2 are the frequencies where the velocity amplitude is equal to 0.707 of its maximum value at ω_0 , then the following equation takes place:

$$\eta_0 = \frac{\Delta\omega}{\omega_0} \quad (1.12)$$

where $\Delta\omega = \omega_2 - \omega_1$. It should be emphasized, however, that this method is valid only for the velocity FRF. For the displacement and acceleration frequency response functions, Eq. (1.12) gives overestimated values of the resonant loss factor η_0 —see Fig. 6. More details about measurement of the damping characteristics can be found in Chapter 15.

1.5 Nonharmonic Forced Vibration

Vibration of real structures is mostly nonperiodic in time. In noise and vibration control, there are two

Figure 6 Estimates of the resonance value of the loss factor of SDOF system using Eq. (1.12) and (1) the velocity FRF, (2) displacement FRF, and (3) acceleration FRF.

main approaches in the analysis of nonharmonic forced vibration—one in frequency domain and another in time domain. The frequency-domain analysis is based on the representation, with the help of the Fourier transform, of any time signal as the superposition of harmonic signals. The general procedure of the analysis is the following. First, the external excitation on the system is decomposed into the sum of time-harmonic components. Then, the response of the system to a harmonic excitation component is obtained. And at last, all the harmonic responses are collected into the final nonharmonic response, which may then be used for solving the needed control problems.

Apply now this procedure to the SDOF system under study acted upon by a nonharmonic external force $f(t)$ and described by Eq. (1.1). Assume that the force is deterministic and square integrable and, therefore, may be represented as the Fourier integral with the spectral density $F(\omega)$:

$$f(t) = \int_{-\infty}^{\infty} F(\omega) e^{i\omega t} d\omega$$

$$F(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} f(t) e^{-i\omega t} dt \quad (1.13)$$

(For details of the Fourier transform and how to compute the spectral density, e.g., by the FFT, see Chapter 42. The case of random excitation is considered in Chapter 13.) Representing in a similar manner displacement $x(t)$ as a Fourier integral and using the response (1.5) of the system to harmonic excitation, one can obtain the following general

equation for the displacement response to arbitrary external force:

$$x(t) = \frac{1}{m} \int_{-\infty}^{\infty} \frac{F(\omega) e^{i\omega t} d\omega}{\omega_0^2 - \omega^2 + 2i\zeta\omega\omega_0} \quad (1.14)$$

where ω_0 and ζ are given in Eq. (1.3).

As an example consider the response of the SDOF system to a very short impulse that acts at moment $t = t_0$ and that mathematically can be written as the Dirac delta function, $f(t) = \delta(t - t_0)$. Solution (1.14) gives in this case the following response, which is known as the *impulse response function*, or *IRF*, and is usually denoted by $h(t - t_0)$:

$$h(t - t_0) = \begin{cases} 0 & \text{for } t < t_0 \\ \frac{1}{m\omega_d} e^{-\zeta\omega_0(t-t_0)} \sin \omega_d(t - t_0) & \text{for } t \geq t_0 \end{cases} \quad (1.15)$$

One can easily verify that IRF (1.15) corresponds to the free vibration (1.2) of the SDOF system with initial condition $x_0 = 0, \dot{x}_0 = 1/m$.

The other approach in the analysis of nonharmonic forced vibration is based on consideration in time domain and employs the impulse response function (1.15):

$$x(t) = \int_{-\infty}^{\infty} f(t_0) h(t - t_0) dt_0 \quad (1.16)$$

Physical meaning of this general equation is the following. An external force may be represented as the superposition of infinite number of δ impulses:

$$f(t_0) = \int_{-\infty}^{\infty} f(\tau) \delta(\tau - t_0) d\tau$$

Since the response to the impulse $f(\tau) \delta(\tau - t_0)$ is equal to $f(t_0) h(t - t_0)$, the superposition of the responses to all the impulses is just the response (1.16). Equation (1.16) is also called the integral of Duhamel.

As an example consider again forced harmonic vibration of the SDOF system, but this time assume that the harmonic force, say of frequency ω_0 , begins to act at $t = 0$:

$$f(t) = \begin{cases} 0 & \text{for } t < 0 \\ f_0 \cos \omega_0 t & \text{for } t \geq 0 \end{cases}$$

Assume also that before $t = 0$ the system was at rest. Then, with the help of the integral of Duhamel (1.16), one obtains the displacement response as

$$x(t) = \frac{f_0}{c\omega_0} \left(\sin \omega_0 t - \frac{\omega_0}{\omega_d} e^{-\zeta\omega_0 t} \sin \omega_d t \right)$$

This response consists of two components. The first component, $(f_0/c\omega_0) \sin \omega_0 t$, presents the steady-state forced vibration (1.5) at frequency ω_0 . The second component is free vibration at natural frequency ω_d caused by the sudden application of the external force. At the initial moment $t = 0$, both components have comparable amplitudes. As time increases the free vibration component decreases exponentially, while the amplitude of the steady-state component remains unchanged. For example, if the resonance loss factor of the system is $\eta_0 = 0.05$ (as in Fig. 1), the free vibration amplitude becomes less than 5% of the steady-state amplitude after 19 periods passed ($t \geq 19T$, where $T = 2\pi/\omega_d$) and less than 1% for $t \geq 30T$.

2 MULTI-DEGREE-OF-FREEDOM SYSTEMS

Multi-degree-of-freedom systems (designated here as NDOF systems) are linear vibratory systems that require more than one variable to completely describe their vibrational behavior. For example, vibration of a machine on resilient supports is a combination of its motions in various directions. If the machine may be considered as a rigid body (this is the case of low frequencies), one needs six variables (three translational and three rotational deflections from the equilibrium position) to describe the current position of the machine. This machine-isolator system is said to have six degrees of freedom (DOFs). The minimum number of variables needed for the description of a vibratory system defines its number of DOFs.

In this section, discrete vibratory systems with finite numbers of DOFs are considered. Many modern methods of vibration analysis of engineering structures, such as the finite element method, modal analysis, and others, are based on vibration analysis of NDOF systems. The number of DOFs of such a system depends on the structure as well as on the frequency range. The machine mentioned above might undergo deformations at higher frequencies, and this will require additional variables for adequate description. However, it is not reasonable to increase the number N of DOFs beyond a certain limit, since computational efforts increase, in general case, as N^3 . Other methods of analysis, for example, the use of continuous models having infinite number of DOFs, may often be more appropriate.

Many properties of vibratory NDOF systems are identical to those of SDOF systems: NDOF system has N natural frequencies, free vibrations are exponentially decaying harmonic motions, forced vibration may demonstrate resonance and antiresonance, and the like. There are also specific properties that are absent in SDOF system vibration being the consequence of the multi-DOF nature. These are the existence of normal modes of vibration, their orthogonality, decomposition of arbitrary vibration into normal modes, and related properties that constitute the basis of modal analysis.

2.1 Equations of Motion

Consider a general mass-spring-dashpot system with N degrees of freedom vibration that is completely

described by N displacements, which, for simplicity, are written as one displacement vector:

$$\mathbf{x}(t) = [x_1(t), x_2(t), \dots, x_N(t)]^T \quad (2.1)$$

where the upper index T means transposition. Vibration of the system is governed by the well-known set of N linear ordinary differential equations:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{f}(t) \quad (2.2)$$

where

$$\mathbf{f}(t) = [f_1(t), f_2(t), \dots, f_N(t)]^T \quad (2.3)$$

is the vector of external forces acting on the masses, $\mathbf{M} = [m_{jn}]$ is a symmetric ($m_{jn} = m_{nj}$) positive definite inertia matrix of order N , $\mathbf{C} = [c_{jn}]$ is a symmetric nonnegative damping $N \times N$ matrix, the square stiffness matrix $\mathbf{K} = [k_{jn}]$ is also assumed symmetric and nonnegative. The assumption of symmetry means that, in the system, there are no gyroscopic elements that are described by antisymmetric matrices ($c_{jn} = -c_{nj}$). The symmetry of the matrices also means that the Maxwell-Betti reciprocity theorem is valid for the system. (The theorem states²: the dynamic response, i.e., the displacement amplitude and phase, of j th mass to a harmonic external force applied to n th mass is equal to the dynamic response of n th mass to the same force applied to j th mass.) A more general case of NDOF systems with nonsymmetric matrices is discussed in Section 2.4.

Example 2DOF system (Fig. 7) consists of two masses m_1 and m_2 moving in vertical direction, two springs of stiffness k_1 and k_2 , and two dashpots with damping coefficients c_1 and c_2 . The two variables for description of system vibration are displacements $x_1(t)$ and $x_2(t)$ of the two masses. External force $f_1(t)$ acts on the first mass while the second mass is free of loading. The system vibration is governed by the set of ordinary differential equations (2.2) with system matrices

$$\mathbf{M} = \begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \quad \mathbf{C} = \begin{bmatrix} c_1 + c_2 & -c_2 \\ -c_2 & c_2 \end{bmatrix} \quad (2.4)$$

$$\mathbf{K} = \begin{bmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_2 \end{bmatrix}$$

and vector (2.3) that has two components, $f_1(t) \neq 0$ and $f_2(t) = 0$.

2.2 Free Vibration

Free vibration of NDOF systems corresponds to solutions of a homogeneous set of linear equations (2.2) with $\mathbf{f}(t) = 0$. As the coefficients of the equations are assumed independent of time, the solutions are sought in the form

$$\mathbf{x}(t) = \text{Re}(\mathbf{x}e^{j\omega t}) \quad (2.5)$$

Figure 7 Example of a two-degree-of-freedom system. Arrows indicate the positive direction of the force and displacements.

where $\mathbf{x} = [x_1, x_2, \dots, x_N]^T$ is the vector of the complex amplitudes of the mass displacements.

Undamped System Consider first the undamped system for which matrix \mathbf{C} is the null matrix. Substitution of (2.5) into Eq. (2.2) leads to the following set of algebraic equations with respect to the complex amplitudes:

$$(\mathbf{K} + \gamma^2 \mathbf{M})\mathbf{x} = 0 \quad (2.6)$$

In linear algebra, this problem is known as the generalized eigenvalue problem.³ A solution to Eq. (2.6) exists only for certain values of parameter γ that are the roots of the characteristic equation $\det(\mathbf{K} + \gamma^2 \mathbf{M}) = 0$. For matrices \mathbf{M} and \mathbf{K} with the special properties indicated above, all the roots of the characteristic equation are pure imaginary:

$$\gamma_n^{(1,2)} = \pm i\omega_{0n} \quad n = 1, 2, \dots, N \quad (2.7)$$

where the real-valued nonnegative *undamped natural frequencies*

$$\{\omega_{01}, \omega_{02}, \dots, \omega_{0N}\} \quad (2.8)$$

constitute the *spectrum* of the system. Corresponding to each natural frequency ω_{0n} , the eigenvector \mathbf{x}_n of the problem (2.6) exists. Its components are real valued and equal to the amplitudes of the mass displacements when the system is vibrating at frequency ω_{0n} . The pair

$\{\omega_{0n}, \mathbf{x}_n\}$ defines the *n*th *natural* or *normal mode* of vibration, the vector \mathbf{x}_n being termed the *mode shape*.

Orthogonality Relations The theory³ says that the mode shapes are \mathbf{M} -orthogonal and \mathbf{K} -orthogonal, that is, orthogonal with weights \mathbf{M} and \mathbf{K} , so that

$$\mathbf{x}_j^T \mathbf{M} \mathbf{x}_n = \delta_{jn} \quad \mathbf{x}_j^T \mathbf{K} \mathbf{x}_n = \omega_{0n}^2 \delta_{jn} \quad (2.9)$$

where δ_{jn} is the symbol of Kroneker that equals to unity if $j = n$ and to zero if $j \neq n$.

Mathematically, orthogonality relations (2.9) mean that two symmetric matrices, \mathbf{M} and \mathbf{K} , may be simultaneously diagonalized by the *congruence transformation* with the help of the *modal matrix* $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_N]$, composed of the mode shape vectors \mathbf{x}_n :

$$\mathbf{X}^T \mathbf{M} \mathbf{X} = \mathbf{I} \quad \mathbf{X}^T \mathbf{K} \mathbf{X} = \mathbf{\Omega}_0^2 = \text{diag}(\omega_{01}^2, \dots, \omega_{0N}^2) \quad (2.10)$$

(Note that the modal matrix also diagonalizes matrix $\mathbf{M}^{-1}\mathbf{K}$ by the *similarity transformation*: $\mathbf{X}^{-1}(\mathbf{M}^{-1}\mathbf{K})\mathbf{X} = \mathbf{\Omega}_0^2$). As a consequence, the transition from displacement variables (2.5) to the *modal coordinates* $\mathbf{q} = [q_1, \dots, q_N]^T$

$$\mathbf{x} = \mathbf{X} \mathbf{q} \quad (2.11)$$

transforms the set of equations (2.6) into the following set:

$$(\mathbf{\Omega}_0^2 + \gamma^2 \mathbf{I})\mathbf{q} = 0 \quad (2.12)$$

the matrix of which is diagonal, and \mathbf{I} is the identity matrix. Set (2.12) principally differs from set (2.6): in Eqs. (2.12), the modal coordinates are uncoupled, while in Eqs. (2.6), the displacement coordinates are coupled. Therefore, each equation of set (2.12) may be solved with respect to the corresponding modal coordinate independently from other equations.

Physically, the orthogonality relations (2.9), (2.10) together with Eqs. (2.12) mean that the normal modes are independent from each other. If a normal mode of certain natural frequency and mode shape exists at a given moment, it will exist unchanged all the later time without interaction with other modes. In other words, an NDOF system is equivalent to N uncoupled SDOF systems.

Free Vibration If $\mathbf{x}_0 = \mathbf{x}(0)$ and $\dot{\mathbf{x}}_0 = \dot{\mathbf{x}}(0)$ are initial values of the displacements and velocities, the time history of free vibration is described by the sum of the normal modes

$$\mathbf{x}(t) = \sum_{n=1}^N \left(a_n \cos \omega_{0n} t + \frac{b_n}{\omega_{0n}} \sin \omega_{0n} t \right) \mathbf{x}_n \quad (2.13)$$

where the decomposition coefficients are obtained using the orthogonality relation (2.9) as

$$a_n = \mathbf{x}_n^T \mathbf{M} \mathbf{x}_0 \quad b_n = \mathbf{x}_n^T \mathbf{M} \dot{\mathbf{x}}_0$$

It is seen from these equations that in order to excite a particular normal mode, say j th mode, apart from other modes, the initial disturbances \mathbf{x}_0 and/or $\dot{\mathbf{x}}_0$ should be equal exactly to j th mode shape.

NDOF System with Proportional Damping

When the NDOF system is damped, its free vibration amplitudes satisfy the following set of linear algebraic equations:

$$(\mathbf{M}\gamma^2 + \mathbf{C}\gamma + \mathbf{K})\mathbf{x} = \mathbf{0} \quad (2.14)$$

The simplest for analysis is the case of the so-called *proportional damping*, or Rayleigh damping, when the damping matrix is a linear combination of the mass and stiffness matrices:

$$\mathbf{C} = 2\alpha\mathbf{M} + 2\beta\mathbf{K} \quad (2.15)$$

Equation (2.14), in this case, can be transformed into

$$(\mathbf{K} + \mu^2\mathbf{M})\mathbf{x} = \mathbf{0} \quad \mu^2 = \gamma^2 \frac{1 + 2\alpha/\gamma}{1 + 2\beta\gamma}$$

This equation coincides with Eq. (2.6) for undamped system. Hence, the parameter μ^2 may be equal to one of N real-valued quantities $\mu_n^2 = -\omega_{0n}^2$ —see Eq. (2.7), while the parameter γ is complex valued:

$$\begin{aligned} \gamma_n^{(1,2)} &= -\zeta_n\omega_{0n} \pm i\omega_n \quad n = 1, 2, \dots, N \\ \zeta_n &= \alpha/\omega_{0n} + \beta\omega_{0n} \quad \omega_n = \omega_{0n}\sqrt{1 - \zeta_n^2} \end{aligned} \quad (2.16)$$

The mode shapes \mathbf{x}_n coincide with the undamped mode shapes, that is, they are real valued and \mathbf{M} -orthogonal and \mathbf{K} -orthogonal.

Free vibration of the damped NDOF system is the superposition of N undamped normal modes, amplitudes of which exponentially decrease with time. The time history of free vibration is described by

$$\begin{aligned} \mathbf{x}(t) = \sum_{n=1}^N e^{-\zeta_n\omega_{0n}t} & \left(a_n \cos \omega_n t \right. \\ & \left. + \frac{b_n + \zeta_n\omega_{0n}a_n}{\omega_n} \sin \omega_n t \right) \mathbf{x}_n \end{aligned} \quad (2.17)$$

where coefficients a_n and b_n are obtained from the initial conditions as in Eq. (2.13), modal damping ratios ζ_n and natural frequencies being given in Eq. (2.16). Note that if a system is undamped or it has a Rayleigh damping, all its inertia elements move, during free vibration, in phase or in counterphase as seen from Eqs. (2.13) and (2.17).

NDOF System with Nonproportional Damping

When damping in the NDOF system is nonproportional, the characteristic equation of set (2.14), $\Delta(\gamma) = \det(\gamma^2\mathbf{M} + \gamma\mathbf{C} + \mathbf{K} = 0)$, has N complex-conjugate

pairs of roots (2.16), just as in the case of proportional damping, though with more complicated expressions for the damping ratios ζ_n and natural frequencies ω_n . The main difference from the case of proportional damping is that the eigenvectors of the problem (2.14) are complex valued and constitute N complex-conjugate pairs. Physically, it means that each mass of the system has its own phase of free vibration, which may differ from 0 and π . Another difference is that these complex eigenvectors do not satisfy the orthogonality relations (2.9). This makes the solution (2.17) incorrect and requires more general approaches to treating the problem. Two such approaches are outlined in what follows.

The first and often used approach is based on conversion of N equations of the second order (2.2) into a set of $2N$ equations of the first order. This can be done, for example, by introducing the state-space $2N$ vector $\mathbf{s}(t) = [\mathbf{x}^T(t), \dot{\mathbf{x}}^T(t)]^T$. Set (2.2) is then cast into

$$\begin{aligned} \mathbf{A}\dot{\mathbf{s}}(t) + \mathbf{B}\mathbf{s}(t) &= \mathbf{g}(t) \\ \mathbf{A} &= \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \mathbf{M} \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} \mathbf{0} & -\mathbf{I} \\ \mathbf{K} & \mathbf{C} \end{bmatrix}, \\ \mathbf{g}(t) &= \begin{bmatrix} \mathbf{0} \\ \mathbf{f}(t) \end{bmatrix} \end{aligned} \quad (2.18)$$

Seeking a solution of homogeneous equations (2.18) in the form $\mathbf{s}(t) = \mathbf{s} \exp(\gamma t)$, one can obtain $2N$ complex eigenvalues and $2N$ eigenvectors \mathbf{s}_n . Simultaneously, it is necessary to consider the adjoint to (2.18) set of $2N$ equations:

$$-\mathbf{A}^*\dot{\mathbf{r}}(t) + \mathbf{B}^*\mathbf{r}(t) = \mathbf{0} \quad (2.19)$$

and to find its eigenvectors \mathbf{r}_n . The asterisk denotes the Hermitian conjugate, that is, complex conjugate and transposition. The eigenvectors of the two adjoint problems, \mathbf{s}_n and \mathbf{r}_n , are biorthogonal with weight \mathbf{A} and weight \mathbf{B}

$$r_j^* \mathbf{A} \mathbf{s}_m = \delta_{jm} \quad \mathbf{r}_j^* \mathbf{B} \mathbf{s}_m = \gamma_m \delta_{jm} \quad (2.20)$$

Decomposing the initial $2N$ vector $\mathbf{s}_0 = \mathbf{s}(0)$ into eigenvectors \mathbf{s}_n and using the orthogonality relations (2.20), one can obtain the needed equation for the free vibration. This equation is mathematically exact, although not transparent physically. More details of this approach can be found elsewhere.⁴

Another approach is physically more familiar but is approximate mathematically. The solution of Eq. (2.2) is sought as the superposition of the undamped natural modes, that is, in the form (2.17). The approximation is to neglect those damping terms that are nonproportional and retain the proportional ones. The accuracy of the approximation depends on how the actual damping is close to the Rayleigh damping. In the illustrative example of the next subsection, both

approaches will be used for treating forced vibration of a 2DOF system.

2.3 Forced Vibration

Forced vibration of NDOF systems corresponds to solutions of inhomogeneous equation (2.2) with a nonzero excitation force, $\mathbf{f}(t) \neq 0$.

Consider first the harmonic excitation $\mathbf{f}(t) = \text{Re}[\mathbf{f} \exp(-i\omega t)]$. The steady-state response of the system is also a vector time function of the same frequency, $\mathbf{x}(t) = \text{Re}[\mathbf{x} \exp(-i\omega t)]$. The vector of the complex displacement amplitudes \mathbf{x} is determined from Eq. (2.2):

$$\mathbf{x} = [\mathbf{K}(\omega)]^{-1} \mathbf{f} = \mathbf{G}(\omega) \mathbf{f} \quad (2.21)$$

$$\mathbf{K}(\omega) = \mathbf{K} - \omega^2 \mathbf{M} - i\omega \mathbf{C}$$

where the $N \times N$ matrix $\mathbf{G}(\omega)$ of the dynamic flexibilities is the inverse of the dynamic stiffness matrix $\mathbf{K}(\omega)$. For a given external force vector \mathbf{f} , solution (2.21) gives the amplitudes and phases of all the mass displacements. As each element of the flexibility matrix is the ratio of two polynomials of frequency ω , the denominator being equal to the characteristic expression $\det \mathbf{K}(\omega)$, the frequency response functions (2.21) demonstrate maxima near the system natural frequencies (resonance) and minima between them (antiresonance)—see, for example, Fig. 8.

When the number of DOFs of the mechanical system is not small, *modal analysis* is more appropriate in practice for analyzing the system vibration. It is

based on the representation of solution (2.21) in a series of the undamped normal modes and decoupling the NDOF system into N separate SDOF systems. The basic concepts of the modal analysis are the following (its detailed presentation is given in Chapter 47).

Let $\{\omega_{0n}, \mathbf{x}_n\}$ be the undamped normal modes, $n = 1, 2, \dots, N$ —see the previous subsection. Transforming the physical variables $\mathbf{x}(t)$ into modal coordinates $\mathbf{q}(t) = [q_1(t), \dots, q_N(t)]^T$ as in Eq. (2.11) and using the orthogonality relations (2.10), one can obtain from Eq. (2.2) the following N ordinary differential equations:

$$\ddot{\mathbf{q}}(t) + \mathbf{D}\dot{\mathbf{q}}(t) + \mathbf{\Omega}_0^2 \mathbf{q}(t) = \mathbf{X}^T \mathbf{f}(t) \quad (2.22)$$

where $\mathbf{D} = \mathbf{X}^T \mathbf{C} \mathbf{X}$.

If damping is proportional, the matrices \mathbf{D} and $\mathbf{\Omega}_0^2$ are both diagonal, all the equations (2.22) are independent, and the modal variables are decoupled. The vibration problem for the NDOF system is thus reduced to the problem for N separate SDOF systems. One can obtain in this case the following equation for the flexibility matrix (2.21) decomposed into the modal components:

$$\mathbf{G}(\omega) = \mathbf{X}(\mathbf{\Omega}_0^2 - \omega^2 \mathbf{I} - 2i\omega \mathbf{D})^{-1} \mathbf{X}^T$$

$$= \sum_{n=1}^N \frac{\mathbf{x}_n \mathbf{x}_n^T}{\omega_{0n}^2 - \omega^2 - 2i\omega \omega_{0n} \zeta_n} \quad (2.23)$$

Figure 8 (a) Amplitude–frequency curves and (b) phase–frequency curves for the displacement of the first mass of 2DOF system (Fig. 7): exact solution (2.21)—solid lines; approximate solution with the proportional damping—dashed lines; dimensionless frequency is ω/ω_1 .

It is instructive to compare solution (2.21), (2.23) with similar solution (1.5) for an SDOF system. It is seen from Eq. (1.5) that to put an SDOF system into resonance, *one condition* should be met—the excitation frequency should be close to the system natural frequency. For NDOF systems it is not sufficient. To put an NDOF system into resonance, *two conditions* should be met as it follows from Eq. (2.23): beside the closeness of the frequencies, the shape of the external force should be close to the corresponding mode shape. If the force shape is orthogonal to the mode shape, $\mathbf{x}_n^T \mathbf{f} = 0$, the response is zero even at the resonance frequency.

The response of the NDOF system to a non-harmonic excitation can be obtained from the harmonic response (2.21), (2.23) with the help of the Fourier transformation as is done for SDOF system in Section 1.4. In particular, if the external force is an impulsive function $\mathbf{f}(t) = \mathbf{f} \delta(t - t_0)$, the system response is described by the impulse response matrix function, which is the Fourier transform of the flexibility matrix

$$\mathbf{H}(t - t_0) = \begin{cases} \mathbf{0} & \text{if } t < t_0 \\ \sum_{n=1}^N e^{-\zeta_n \omega_{0n} (t-t_0)} \frac{\sin \omega_n (t-t_0)}{\omega_n} \mathbf{x}_n \mathbf{x}_n^T & \text{if } t \geq t_0 \end{cases} \quad (2.24)$$

The time response to an arbitrary excitation $\mathbf{f}(t)$ can then be computed as

$$\mathbf{x}(t) = \int_{-\infty}^{\infty} \mathbf{H}(t - t_0) \mathbf{f}(t_0) dt_0 \quad (2.25)$$

Equations (2.24) and (2.25) completely solve the problem of forced nonharmonic vibrations of undamped and proportionally damped NDOF systems.

If damping is not proportional, the coordinate transformation (2.11) diagonalizes only the inertia and stiffness matrices [see Eqs. (2.10)] but not the damping matrix. In this case, Eq. (2.22) is coupled through the nondiagonal elements of matrix \mathbf{D} , and the NDOF system cannot be represented as N independent SDOF systems. One commonly used approach to treating the problem is to obtain the approximate solution by neglecting the off-diagonal elements of matrix \mathbf{D} and retaining only its diagonal elements, which correspond to the proportional damping components and using Eqs. (2.23) to (2.25).

Another approach is to use the *complex modal analysis* based on introducing the state-space coordinates—see Eqs. (2.18) to (2.20). This approach leads to exact theoretical solutions of the problem, but it is more laborious than the approximate classical modal analysis (because of doubling the space dimension) and difficult for practical implementation.⁴

Example Consider forced harmonic vibration of the 2DOF system in Fig. 7 under the action of force $f_1 =$

$1 \cdot \exp(-i\omega t)$ applied to the first mass. Let the parameters (2.4) be $m_1 = 0.5$ kg, $m_2 = 0.125$ kg, $k_1 = 3 \times 10^3$ Nm⁻¹, $k_2 = 10^3$ Nm⁻¹, $c_1 = 5$ Ns m⁻¹, and $c_2 = 1$ Ns m⁻¹. The eigenvalues of the undamped problem, $\omega_{01}^2 = 4 \times 10^3$ s⁻² and $\omega_{02}^2 = 1.2 \times 10^4$ s⁻², correspond to the undamped natural frequencies, 10 and 17 Hz. The normal mode shapes are $\mathbf{x}_1 = [1, 2]^T$, $\mathbf{x}_2 = [-1, 2]^T$. Since the damping of the system is not proportional, matrix \mathbf{D} in Eq. (2.22) is not diagonal:

$$\mathbf{D} = \mathbf{X}^T \mathbf{C} \mathbf{X} = \begin{bmatrix} 6 & -2 \\ -2 & 14 \end{bmatrix}$$

Figure 8 presents the amplitude and phase of the first mass displacement as functions of frequency. Solid lines correspond to the exact solution (2.21), while the dashed lines correspond to the approximate solution obtained by neglecting off-diagonal terms of matrix \mathbf{D} . Though the difference between the exact (non-proportional) and approximate (proportional) damping is about 20%, $\|\Delta \mathbf{C}\|/\|\mathbf{C}\| = 0.2$, where $\|\mathbf{C}\|$ is the Euclidean matrix norm,³ the difference between the solutions is noticeable only at the natural frequencies being less than 0.4% at the resonance frequencies and 20% at the antiresonance frequency.

2.4 General Case

In practice, a linear vibratory system may contain gyroscopic (rotating) elements, parts of nonmechanical nature, control devices, and the like. As a result, its mass, damping, and stiffness matrices in Eq. (2.2) may be nonsymmetric and not necessarily positive definite. For such systems, the classical modal analysis, based on simultaneous diagonalization of mass and stiffness symmetric matrices by the congruence transformation (2.10), is not valid. One general approach to treating the problem in this case is to use the complex modal analysis in $2N$ -dimensional state space⁴—see Eqs. (2.18) to (2.20). However, for large N , it may be more appropriate to use a simpler and physically more transparent method of analysis in N -dimensional “Lagrangian” space. This method is based on simultaneous diagonalization of two square matrices by the so-called *equivalent transformation*.³ It represents a direct extension of the classical modal analysis and may be applied to practically every real situation. In what follows, the basic concepts of this method, which may be termed as *generalized modal analysis*, are briefly expounded. A detailed description can be found in the literature.⁵

Let \mathbf{M} be a square inertia matrix of order N that, without loss of generality, is assumed nonsingular and \mathbf{K} be a stiffness $N \times N$ matrix. They are generally nonsymmetric, and their elements are real valued. For equation of motion (2.2), define two adjoint algebraic generalized eigenvalue problems [compare with Eq. (2.6)]:

$$\mathbf{K} \mathbf{x} = \lambda \mathbf{M} \mathbf{x} \quad \mathbf{K}^T \mathbf{y} = \lambda \mathbf{M}^T \mathbf{y} \quad (2.26)$$

These problems have identical eigenvalues λ_n but different eigenvectors \mathbf{x}_n and \mathbf{y}_n , $n = 1, 2, \dots, N$. (Note that in the literature they are sometimes called the right and left eigenvectors.) By assuming that N eigenvectors \mathbf{x}_n are linearly independent or that the eigenvalues λ_n are distinct, one can derive from Eq. (2.26) the following biorthogonality relations:

$$\mathbf{Y}^T \mathbf{M} \mathbf{X} = \mathbf{I} \quad \mathbf{Y}^T \mathbf{K} \mathbf{X} = \mathbf{\Lambda} \quad (2.27)$$

where

$$\mathbf{\Lambda} = \text{diag}(\lambda_1, \dots, \lambda_N)$$

$$\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_N] \quad \mathbf{Y} = [\mathbf{y}_1, \dots, \mathbf{y}_N]$$

Equations (2.27) mean that the mass and stiffness matrices, \mathbf{M} and \mathbf{K} , may be simultaneously diagonalized by the equivalence transformation with the help of two nonsingular matrices \mathbf{X} and \mathbf{Y} . Hence, the variable transformation

$$\mathbf{x}(t) = \mathbf{X} \mathbf{q}(t) \quad (2.28)$$

completely decouples Eq. (2.2) with $\mathbf{C} = 0$:

$$\ddot{\mathbf{q}}(t) + \mathbf{\Lambda} \mathbf{q}(t) = \mathbf{Y}^T \mathbf{f}(t) \quad (2.29)$$

The eigenvectors \mathbf{x}_n and \mathbf{y}_n may be termed *natural modes* and *adjoint modes*. When eigenvalue λ_n is real positive, the free system motion is harmonic, square root $\sqrt{\lambda_n}$ is the natural frequency, and the corresponding mode shape \mathbf{x}_n has real-valued components (i.e., all masses move in phase or counterphase).

If square matrices \mathbf{M} and \mathbf{K} are symmetric, the eigenvalue problems (2.26) are identical and the problem (2.2) is self-adjoint. In this case, the adjoint eigenvectors \mathbf{y}_n coincide with \mathbf{x}_n and the equivalence transformation (2.27) becomes the congruence transformation (2.10). The classical modal analysis is thus a particular case of the generalized modal analysis based on eqs. (2.26) to (2.29).

It should be noted that the equivalence transformation cannot diagonalize simultaneously three matrices unless the damping matrix \mathbf{C} is a linear combination of \mathbf{M} and \mathbf{K} . Therefore, in general case the transformation (2.28) reduces equation (2.2) into N equations:

$$\ddot{\mathbf{q}}(t) + \mathbf{D} \dot{\mathbf{q}}(t) + \mathbf{\Lambda} \mathbf{q}(t) = \mathbf{Y}^T \mathbf{f}(t) \quad (2.30)$$

that are coupled through off-diagonal elements of matrix $\mathbf{D} = \mathbf{Y}^T \mathbf{C} \mathbf{X}$. An approximate solution to Eq. (2.30) may be obtained by neglecting off-diagonal terms of \mathbf{D} .

3. CONTINUOUS ONE-DIMENSIONAL SYSTEMS

Continuous vibratory systems are used as models of comparatively large vibrating engineering structures and structure elements of uniform or regular geometry.

Beams, plates, and shells are examples of continuous systems. In the systems, the inertia, elastic, and damping parameters are continuously distributed, and the number of degrees of freedom is infinite even if the system size is limited.

Wave motion is the main phenomenon in continuous vibratory systems. Any free or forced vibration of such a system can always be expanded in terms of elementary wave motions. Therefore, in this and following sections, considerable attention is devoted to the properties of waves.

Mathematical description of vibration in continuous systems is based rather on "theory-of-elasticity" and "strength-of-materials" consideration than on mechanical consideration of case of discrete systems. However, the governing equations of motion for most of the existing continuous systems do not originate from the exact equations of elasticity. They are obtained, as a rule, by making certain simplifying assumptions on the kinematics of deformation and using Hamilton's variational principle of least action.

In this section, one-dimensional (1D) continuous vibratory systems are considered in which two of three dimensions are assumed as small compared to the wavelength. A vibration field in a 1D system depends on time and one space coordinate. Examples of 1D systems are thin straight or curved beams (rods, bars, columns, thin-walled members), taut strings (ropes, wires), fluid-filled pipes, and the like. Most attention is paid to waves and vibration in an elastic beam—a widely used element of engineering structures.

3.1 Longitudinal Vibration in Beams

Consider a straight uniform thin elastic beam of cross-sectional area S . Let axis x be directed along the beam and pass through the cross-section centroid (Fig. 9). The main assumptions of the simplest (engineering) theory of longitudinal vibration are the following: plane cross sections remain plane during deformation; the axial displacement u_x and stress σ_{xx} are uniform over cross section, and the lateral stresses are zero. Mathematically, these can be written as

$$\begin{aligned} u_x(x, y, z, t) &= u(x, t) & u_y(x, y, z, t) &= -\nu y u'(x, t) \\ u_z(x, y, z, t) &= -\nu z u'(x, t) \\ \sigma_{xx}(x, y, z, t) &= E u'(x, t) & \sigma_{yy} &= 0 & \sigma_{zz} &= 0 \end{aligned} \quad (3.1)$$

where prime denotes the derivative with respect to x , E and ν are Young's modulus and Poisson's ratio. Equation for the axial stress follows from Hooke's law.² Nonzero lateral displacements, u_y and u_z , are allowed due to the Poisson effect.

Governing Equation and Boundary Conditions

To obtain the governing equation of longitudinal vibration, one should compute the kinetic and potential energies that correspond to hypothesis (3.1) and then employ Hamilton's variational principle. (For a detailed description of the principle see Chapter 11.)

Figure 9 Frame of references and positive direction of the displacement u_j and force F_j , angle of twist θ_j and moment M_j round axis j in a beam of cross-section S , $j = x, y, z$.

The kinetic energy of the beam of length l is

$$T = \frac{1}{2} \rho \int_0^l \iint_S (\dot{u}_x^2 + \dot{u}_y^2 + \dot{u}_z^2) dx dS$$

$$= \frac{1}{2} \rho \int_0^l (S \dot{u}^2 + v^2 I_p \dot{u}^2) dx \quad (3.2)$$

where ρ is the density of the beam material, $I_p = \iint_S (y^2 + z^2) dS$ is the polar moment of the cross section, and the overdot designates the time derivative. The first term of Eq. (3.2) describes the kinetic energy of axial movement and the second term—of the lateral movement. The potential energy of the beam is equal to

$$U = \frac{1}{2} \int_0^l \iint_S \left(\frac{\sigma_{xx}^2}{E} + \frac{\sigma_{xy}^2 + \sigma_{xz}^2}{G} \right) dx dS$$

$$= \frac{1}{2} \int_0^l (E S u'^2 + v^2 G I_p u''^2) dx \quad (3.3)$$

Here G is the shear modulus. The first term of Eq. (3.3) represents the energy of the axial deformation, while

the second term relates to the shear deformation. If only the first terms of Eqs. (3.2) and (3.3) are retained, the following equation can be obtained from the variational principle:

$$E S u''(x, t) - \rho S \ddot{u}(x, t) = -f_x(x, t) \quad (3.4)$$

where $f_x(x, t)$ is the linear density of external axial load. This equation is called the *Bernoulli equation*. Formally, it coincides with the wave equations that describe wave motions in many other structures and media (strings, fluids, solids), but differs from them by the coefficients and physical content.

Vibration of continuous systems should also be described by boundary conditions. For longitudinally vibrating beams, the simplest and most frequently used end terminations are the fixed and free ends with the following boundary conditions:

$$u(l, t) = 0 \quad (\text{fixed end})$$

$$F_x(l, t) = 0 \quad (\text{free end}) \quad (3.5)$$

where l is the end coordinate, and

$$F_x(x, t) = \iint_S \sigma_{xx} dS = E S u'(x, t) \quad (3.6)$$

is the axial force that is transmitted in the beam through cross section x .

Harmonic Wave Motion Consider an elementary longitudinal wave motion in the beam of the form

$$u(x, t) = \text{Re} [u \exp(ikx - i\omega t)]$$

$$= u_0 \cos(kx - \omega t + \varphi) \quad (3.7)$$

Here $k = 2\pi/\lambda$ is the *wave number* or *propagation constant*, λ is the *wavelength*; u_0 is the wave amplitude, $(kx - \omega t + \varphi)$ is the phase of the wave, φ is the initial phase; $u = u_0 \exp(i\varphi)$ is the complex wave amplitude. The wave motion (3.7) is harmonic in time and space coordinates. Any vibration motion of the beam is a superposition of the elementary wave motions of the type (3.7).

One of the most useful characteristics of a wave is its *dispersion* $k(\omega)$, that is, the dependence of the wave number on frequency. To a great extent, dispersion is responsible for the spectral properties of finite continuous systems, and it usually needs to be studied in detail. Substitution of (3.7) into the Bernoulli equation (3.4) yields the *dispersion equation*:

$$k^2 - k_E^2 = 0 \quad k_E = \omega \sqrt{\frac{\rho}{E}} = \frac{\omega}{c_E} \quad (3.8)$$

which just relates the wavenumber to frequency. Equation (3.8) has two roots, $k_{1,2} = \pm k_E$, which

correspond to the waves (3.7) propagating in positive (sign +) and negative (sign -) directions; k_E and c_E are called the longitudinal wavenumber and velocity. It is seen that the wavenumber is a linear function of frequency.

Three types of velocities are associated with a wave. Each phase of the wave $kx - \omega t + \phi = \text{constant}$ propagates with the *phase velocity*

$$c_{\text{ph}} = \frac{\omega}{k} = \sqrt{\frac{E}{\rho}} = c_E \quad (3.9)$$

If the wave amplitude u is a smooth function of x , the envelope $u(x)$ propagates with the *group velocity*⁶:

$$c_{\text{gr}} = \frac{\partial \omega}{\partial k} \quad (3.10)$$

which, for the beam, is equal to the phase velocity c_{ph} . One more velocity is the *energy velocity*. It is defined as the ratio of the time-average power flow across a cross section, $P(x) = \text{Re}(-F_x \dot{u}^*)$ to the linear density of the time-average total energy $E(x)$, $c_{\text{en}} = P(x)/E(x)$. It can be shown that for longitudinal wave (3.7) the velocity of energy propagation is equal to the group velocity, $c_{\text{en}} = c_{\text{gr}}$. In fact, the equivalence of the group and energy velocities takes place for all known systems and media.⁷ Note that the dispersion (3.8) can also be interpreted as independence of the three longitudinal velocities on frequency.

Consideration of propagation of waves (3.7) allows one to solve some practical problems. As an example, consider the wave reflection at the beam end. Since the phase velocity (3.9) does not depend on frequency, a disturbance of any shape propagates along the beam without distortion. For example, if at moment $t = 0$ there is an impulse of the space shape $u(x, 0) = \psi(x)$ propagating in positive direction, it will continue to propagate at later time with speed c_E pertaining its shape, $u(x, t) = \psi(x - c_E t)$. When such an impulse meets the fixed end, it reflects with the same shape but with opposite sign [because of boundary condition (3.5)]. Therefore, the stresses of the reflected impulse are identical to those of the incident impulse giving the *double* stress values at the fixed beam termination. When the impulse meets the free end [see boundary condition (3.5)], its shape pertains but the doubling is observed for displacement, and the reversal is associated with the stresses: Compression reflects as tension and vice versa. This explains, for example, the phenomenon when a part of a beam made of a brittle material may be torn at the free end due to tensile fracture. The phenomenon is known in ballistic and sometimes used in material strength tests.

Free Vibration of a Finite Beam Consider now a beam of length l . Free harmonic vibration is a

combination of elementary waves (3.7):

$$u(x, t) = \text{Re}[(ae^{ik_E x} + be^{-ik_E x})e^{-i\omega t}]$$

where a and b are the complex wave amplitudes that are determined from the boundary conditions at the ends. Let both ends be fixed, $u(0, t) = u(l, t) = 0$. Then one can obtain the *characteristic equation*

$$\frac{\sin k_E l}{k_E l} = 0 \quad \text{or} \quad k_E l = \pi n \quad n = \pm 1, \pm 2, \dots$$

and the relation between the amplitudes, $a + b = 0$. The positive roots of the characteristic equation determine an infinite (countable) number of the normal modes of the beam

$$\{\omega_{0n}, u_n(x)\}_{n=1}^{\infty} \quad (3.11)$$

with undamped natural frequencies $\omega_{0n} = \pi n c_E / l$ and mode shapes $u_n(x) = (l/2)^{-1/2} \sin(\pi n x / l)$. The main properties of the normal modes of the beam (3.11) are very similar to those of NDOF systems: The spectrum is discrete; in each mode all the beam points move in phase or counterphase; the modes are orthogonal:

$$\int_0^l u_m(x) u_n(x) dx = \delta_{mn} \quad (3.12)$$

Free vibration of a finite beam is a superposition of the normal modes (3.11) with the amplitudes that are determined from initial conditions with the help of the orthogonality relation (3.12) just like for NDOF systems—see Eqs. (2.9) and (2.13).

Forced Vibration of a Finite Beam Analysis of forced vibration of beams is also very similar to that of NDOF system vibration. When an external force is harmonic in time, $f_x(x, t) = f_x(x) \exp(-i\omega t)$, the solution is obtained as the expansion in the normal modes (3.11):

$$u(x, t) = \frac{1}{\rho S} \sum_{n=1}^{\infty} \frac{f_{xn} u_n(x) \exp(-i\omega t)}{\omega^2 - \omega_{0n}^2} \quad (3.13)$$

$$f_{xn} = \int_0^l f_x(x) u_n(x) dx$$

If the excitation frequency approaches one of the natural frequencies and the force shape is not orthogonal to the corresponding mode shape, the beam resonance occurs. When the external force is not harmonic in time, the problem may first be cast into the frequency domain by the Fourier transform, and the final result may be obtained by integrating solution (3.13)

over all the frequencies—see also Eqs. (2.23) to (2.25).

Damped Beams There are three main types of losses of the vibration energy in elastic bodies.⁸ The first type is associated with transmission of the vibration energy to the ambient medium by viscous friction or/and by sound radiation from the beam surface. These losses are proportional to the velocity and lead to the additional term $[-2d\dot{u}(x, t)]$ in the Bernoulli equation (3.4), d being the damping coefficient. As a consequence, the free longitudinal wave (3.7) attenuates in space, $k = k_E + i\delta/c_E$, $\delta = d/\rho S$, the natural frequencies of a finite beam become complex, $\omega_n = -i\delta \pm \sqrt{\omega_{0n}^2 - \delta^2}$, and the denominators of each term in solution (3.13) change into $\omega^2 - \omega_{0n}^2 + 2i\omega\delta$.

Losses of the second type are the contact losses at junctions of the beam with other structures. The third type constitutes the internal losses in the beam material. They may be taken into consideration if the axial stress of the beam is assumed to be related to the axial strain as $\sigma_{xx} = E(1 + 2\varepsilon\partial/\partial t)\partial u/\partial x$. This gives the additional term $2\varepsilon\partial^3 u/\partial x^2 \partial t$ in the wave equation (3.4) and leads to complex natural frequencies of the finite beam, and to the solution (3.13) with denominators $\omega^2 - \omega_{0n}^2(1 - 2i\varepsilon\omega)$.

Nonuniform Beams When a beam is nonuniform, for example, has a variable cross-sectional area $S(x)$, the equation of motion is

$$\frac{\partial}{\partial x} \left(ES \frac{\partial u}{\partial x} \right) - \rho S \frac{\partial^2 u}{\partial t^2} = -f(x, t) \quad (3.14)$$

For some functions $S(x)$ this equation may be solved analytically. For example, if $S(x)$ is a linear or quadratic function of x , solutions of Eq. (3.14) are the Bessel functions or spherical Bessel functions. For arbitrarily varying cross section, no analytical solutions exist, and Eq. (3.14) is solved numerically, for example, by the finite element method (FEM).

Improved Theories of Longitudinal Vibrations in Beams A beam may be treated as a three-dimensional body using the exact equations of linear theory of elasticity, that is, avoiding assumptions (3.1). Such exact solutions have been obtained for a circular cylinder and others.⁹

The exact theory says that, in a beam, an infinite number of waves of type (3.7) exist at any frequency. They differ from each other by the values of the propagation constant and shape of cross-section vibrations and are called as the *normal modes* or *normal waves*. At low frequencies, the first normal wave of the symmetric type is a propagating wave with a real propagation constant, while all other normal waves are evanescent waves, that is, have complex propagation constants and therefore attenuate with distance. The Bernoulli longitudinal wave with the propagation constant (3.8) describes only the first normal wave.

Figure 10 Dispersion of normal modes of a narrow beam of rectangular cross section (of height $2H$ and width $2h$, $H/h = 10$) according to the exact theory (solid lines 1 and 2) and to the Bernoulli equation (dashed line B); dimensionless frequency is equal to $k_t H$, where $k_t = \omega(\rho/G)^{1/2}$ is the shear wavenumber and G is the shear modulus of the beam material.

Figure 10 presents the dispersion curves of the normal waves according to the exact theory (solid lines) and the dispersion (3.8)—dashed line B. It is seen that the Bernoulli equation (3.4) provides good description of dispersion and, hence, spectral properties of finite beams in rather wide low-frequency range up to the frequency at which the diameter of the beam cross section is equal to a half of the shear wavelength.

One may try to improve the equation of Bernoulli (3.4) by taking into account new effects of deformation. If, for example, in Eq. (3.2), the kinetic energy of lateral displacement is taken into account, this will add the term $\rho v^2 I_p \ddot{u}''$ to Eq. (3.4). If, in addition, the second term of Eq. (3.3) is taken into account, one more term $v^2 G I_p u^{IV}$ will appear in Eq. (3.4). However, the improvements in the accuracy of vibration analysis caused by these and similar attempts turn out insignificant. The Bernoulli equation (3.4) remains the simplest and the best among the known governing equations of the second and the fourth orders for longitudinal vibration of thin beams.

3.2 Torsional Vibration in Beams

Low-frequency torsional waves and vibration are also described by the wave equations of the type (3.4) or (3.14). According to the theory of Saint-Venant,² the simplest of the existing theories, torsion of a straight uniform beam is composed of two types of deformation: rotation of the cross sections as rigid bodies and deplanation, that is, the axial displacement of the cross-sectional points. Mathematically, this can

be written as the following kinematic hypothesis:

$$\begin{aligned} u_x(x, y, z, t) &= \theta'(x, t)\varphi(y, z) \\ u_y(x, y, z, t) &= -z\theta(x, t) \\ u_z(x, y, z, t) &= y\theta(x, t) \end{aligned}$$

where θ is the angle of twist about the axis x , $\varphi(y, z)$ is the torsional function that satisfies equation $\Delta\varphi = 0$ and boundary condition $\partial\varphi/\partial n = 0$ on the contour of the beam cross section. Taking into account only the kinetic energy of rotation and the potential energy of shear deformations, one can obtain, using the variational principle, the *equation of Saint-Venant* for torsional vibration:

$$GI_S\theta''(x, t) - \rho I_p\ddot{\theta}(x, t) = -m_x(x, t) \quad (3.15)$$

Here, m_x is the linear density of an external torque, I_p is the polar moment of inertia, G and ρ are the shear modulus and density of the material; GI_S is the torsional stiffness. The quantity I_S depends on the torsional function φ . For a beam of a ring cross section (R_1 and R_2 being the outer and inner radii), it is equal to $I_S = (R_1^4 - R_2^4)\pi/2$; for an elliptic cross section (a and b being the semi-axes) $I_S = \pi a^3 b^3 / (a^2 + b^2)$; for a thin-walled beam of open cross section (of length L and thickness h), it equals to $I_S = Lh^3/3$, and so forth.²

The boundary conditions for torsional vibration at end $x = l$ are

$$\begin{aligned} \theta(l, t) &= 0 \quad (\text{fixed end}), \\ M_x(l, t) &= 0 \quad (\text{free end}), \end{aligned} \quad (3.16)$$

where M_x is the torque in cross-section x . It is equal to the moment of the shear stresses:

$$M_x(x, t) = GI_S\theta'(x, t)$$

As the equation of Saint-Venant (3.15) and boundary conditions (3.16) are mathematically identical to the equation of Bernoulli (3.4) and boundary conditions (3.5) for longitudinal waves and vibration, all results obtained in the previous subsection are valid also for torsional waves and vibration and therefore are omitted here.

There are several improved engineering theories of torsional vibrations. Taking account of the potential energy of deformation yields the equation of Vlasov–Timoshenko¹⁰:

$$\begin{aligned} EI_\varphi\theta^{IV} - GI_S\theta'' + \rho I_\varphi\ddot{\theta}'' + \rho I_p\ddot{\theta} &= m_x \\ I_\varphi &= \iint_S \varphi^2 dS \end{aligned}$$

Figure 11 Real and imaginary branches of dispersion of the torsional normal modes in the narrow beam as in Fig. 10 according to the exact theory (solid lines), the Saint-Venant theory (dashed line SV), and Vlasov–Timoshenko equation (dashed lines VT); dimensionless frequency is $k_t H$.

It contains the fourth derivative with respect to x and therefore describes two normal waves. Figure 11 presents the dispersion curves of the torsional normal waves in a narrow beam as in Fig. 10 computed according to the exact theory of elasticity (solid lines) as well as to the Saint-Venant theory (dashed line SV) and to the Vlasov–Timoshenko equation (two dashed lines VT). It is seen that the Saint-Venant equation (3.15) describes adequately the first propagating normal wave in low-frequency range. The equation of Vlasov and Timoshenko describes this wave much more accurately. However, it fails to describe properly the evanescent normal waves with pure imaginary propagation constants. That is why the Saint-Venant equation is preferable in most practical low-frequency problems.

3.3 Flexural Vibration in Beams

Transverse motion of thin beams resulting from bending action produces flexural (or bending) waves and vibration. Their governing equations, even in the simplest case, contain the space derivative of the fourth order thus describing two normal waves at low frequencies. Widely used are two engineering equations of flexural vibration—the classical equation of Bernoulli–Euler and the improved equation of Timoshenko.

Consider a straight uniform thin beam (see Fig. 9) that performs flexural vibration in the plane xz (this is possible when the beam cross section is symmetric with respect to plane xz). The main assumption of the Bernoulli–Euler theory is the following: The plane cross sections initially perpendicular to the axis of the beam remain plane and perpendicular to the

neutral axis in bending; the lateral stresses are zero. Mathematically, the assumption can be written as

$$\begin{aligned} u_x(x, y, z, t) &= -zw'(x, t) & u_y(x, y, z, t) &= 0 \\ u_z(x, y, z, t) &= w(x, t) & \sigma_{xx} &= E\partial u_x/\partial x \end{aligned} \quad (3.17)$$

Computing the kinetic and potential energies as in Eqs. (3.2) and (3.3) and using the variational principle, one can obtain from (3.17) the *Bernoulli–Euler equation* for the lateral displacement $w(x, t)$ of the beam:

$$EI_y w^{IV}(x, t) + \rho S \ddot{w}(x, t) = f_z(x, t) \quad (3.18)$$

where f_z is the linear density of external force, EI_y is the bending stiffness, I_y is the second moment of beam cross section with respect to axis y . Since Eq. (3.18) is of fourth order, there must be two boundary conditions at each end. Typically, they are written as the equalities to zero of two of the following quantities—displacement w , slope w' , bending moment M_y , and shear force F_z :

$$\begin{aligned} M_y(x, t) &= M_y(x=0, t) = -EI_y w''(x, t) \\ F_z(x, t) &= -EI_y w'''(x, t) & I_y &= \iint_S z^2 dS \end{aligned} \quad (3.19)$$

Examples of boundary conditions are presented in Table 2.

The elementary flexural wave motion has the same form as that of other waves [see Eq. (3.7)]:

$$w(x, t) = \text{Re}[w \exp(ikx - i\omega t)] \quad (3.20)$$

After substitution of this into a homogeneous equation (3.18), one obtains the dispersion equation

$$k^4 = \omega^2(\rho S/EI_y) = k_0^4 \quad (3.21)$$

that relates the wavenumber k to frequency ω , and k_0 is called the flexural wavenumber. Equation (3.21) has four roots, $\pm k_0$ and $\pm ik_0$. Hence, two different types of waves (3.20) exist in the Bernoulli–Euler beam (positive and negative signs mean positive and negative directions of propagation or attenuation along axis x). The first type, with real-valued wavenumbers, corresponds to flexural waves propagating without attenuation. The second type, with imaginary wavenumbers, corresponds to evanescent waves that exponentially decay with the space coordinate x .

The phase velocity of the propagating flexural wave depends on frequency:

$$c_{ph} = \frac{\omega}{k} = \omega^{1/2} \left(\frac{EI_y}{\rho S} \right)^{1/4}$$

The higher the frequency the greater is the phase velocity. The group velocity and, hence, the energy velocity, is twice the phase velocity, $c_{gr} = \partial\omega/\partial k = 2c_{ph}$. Dependence c_{ph} on frequency leads to distortion of impulses that may propagate along the beam. Let, for example, a short and narrow impulse be excited at moment $t = 0$ near the origin $x = 0$. Since the impulse has a broad-band spectrum, an observer at point x_0 will detect the high-frequency components of the impulse practically immediately after excitation, while the low-frequency components will be arriving at x_0 for a long time because of their slow speed. The impulse, thus, will be spread out in time and space due to dispersive character of flexural wave propagation in beams.

In reality, the phase and group velocities cannot increase without limit. The Bernoulli–Euler theory of flexural vibration is restricted to low frequencies and to smooth shapes of vibration. Comparison against exact solutions shows that the frequency range of the theory validity is limited to the frequency at which the shear wavelength of the beam material is 10 times the dimension D of the beam cross section, and the flexural wavelengths should not be shorter than approximately $6D$ —see Fig. 12.

Timoshenko Equation An order of magnitude wider is the frequency range of validity of the Timoshenko theory for flexural vibration of beams. The theory is based on the following kinematic hypothesis:

$$\begin{aligned} u_x(x, y, z, t) &= z\theta_y(x, t) & u_y(x, y, z, t) &= 0 \\ u_z(x, y, z, t) &= w(x, t) \end{aligned} \quad (3.22)$$

Figure 12 Real and imaginary branches of dispersion of the flexural normal modes in the narrow beam as in Fig. 10 according to the exact theory (solid lines), the Bernoulli–Euler theory (dashed lines *BE*), and to the Timoshenko equation (dashed lines *T*); dimensionless frequency is $k_t H$.

Table 2 Natural Frequencies of Flexurally Vibrating Bernoulli–Euler Beams $\left(\xi = kl, f_n [\text{Hz}] = \frac{\xi_n^2}{2\pi l^2} \left(\frac{EI}{\rho S} \right)^{1/2} \right)$

Beam	Boundary Conditions	Characteristic Equation	First Four Roots of the Characteristic Equation ($n = 1, 2, 3, 4$)	Asymptotic Roots of the Characteristic Equation ($n > 4$)
Free 	$F(0) = 0$ $M(0) = 0$ $F(l) = 0$ $M(l) = 0$	$\xi^4 (1 - \cosh \xi \cdot \cos \xi) = 0$	0 4.730 7.853 10.996	$\pi n - \frac{\pi}{2}$
Pinned 	$w(0) = 0$ $M(0) = 0$ $w(l) = 0$ $M(l) = 0$	$\frac{\sin \xi}{\xi} = 0$	3.142 6.283 9.425 12.566	πn
Clamped 	$w(0) = 0$ $w'(0) = 0$ $w(l) = 0$ $w'(l) = 0$	$\frac{1 - \cosh \xi \cdot \cos \xi}{\xi^4} = 0$	4.730 7.853 10.996 14.137	$\pi n + \frac{\pi}{2}$
Cantilever 	$w(0) = 0$ $w'(0) = 0$ $F(l) = 0$ $M(l) = 0$	$1 + \cosh \xi \cdot \cos \xi = 0$	1.875 4.694 7.855 10.996	$\pi n - \frac{\pi}{2}$

Here, θ_y is the angle of rotation about axis y , which is not generally equal to $(-w')$ as in the Bernoulli–Euler theory—see Eq. (3.17). This means that plane cross-sections initially perpendicular to the beam axis, remain plane, but they are no longer perpendicular to the neutral axis during bending. In other words, the shear deformations are possible in the Timoshenko beam. Computing the kinetic energy of the lateral and rotational movement and the potential energy of pure bending and shear deformation one can obtain, with the help of the variational principle, the *Timoshenko equations*:

$$\begin{aligned}\rho S \ddot{w}(x, t) &= qGS(w'' + \theta_y') + f_z(x, t) \\ \rho I_y \ddot{\theta}_y(x, t) &= EI_y \theta_y'' - qGS(w' + \theta_y)\end{aligned}\quad (3.23)$$

Function f_z in Eq. (3.23) is the linear density of an external force. The boundary conditions are the same as for the Bernoulli–Euler equation, but the bending moment and shear force are defined by the equations:

$$\begin{aligned}M_y(x, t) &= EI_y \theta_y'(x, t) \\ F_z(x, t) &= qGS[w'(x, t) + \theta_y(x, t)]\end{aligned}\quad (3.24)$$

From the point of view of linear theory of elasticity, there exists a contradiction between the two assumptions of the Timoshenko theory, namely between the plane cross-section hypothesis (3.22) and existence of shear stresses σ_{xz} . For that reason, Timoshenko introduced the *shear coefficient* q replacing elastic modulus G by qG .¹¹ This coefficient, together with the rotatory inertia taken into account, considerably improves the spectral properties of beams and makes Eqs. (3.23) the most valuable in flexural vibration theory.

In Fig. 12 presented are the dispersion curves of a beam of the rectangular cross section ($H/h = 10$). Curves 1 and 2 are computed on the basis of linear theory of elasticity, curves *BE* correspond to dispersion (3.21) of the Bernoulli–Euler beam, and curves *T* are described by the equations

$$2k_{1,2}^2 = k_E^2 + \frac{k_t^2}{q} \pm \left[\left(k_E^2 - \frac{k_t^2}{q} \right) + 4k_0^4 \right]^{1/2} \quad (3.25)$$

that are obtained from Eqs. (3.23) for wave (3.20). The shear coefficient value $q = \pi^2/12$ is chosen from the coincidence of the cutoff frequencies in the real beam and its model. It is seen from Fig. 12 that the frequency range of validity of the Timoshenko theory is much wider than that of the Bernoulli–Euler theory. It is valid even at frequencies where the shear wavelength of the beam material is comparable with the dimension of the beam cross section.

As for free and forced flexural vibrations of finite beams, their analysis is very similar to that of NDOF systems and longitudinal vibrations of beams. The common procedure is the following.¹² First,

the undamped normal modes are determined. For that, the general solution of homogeneous Eq. (3.18) or Eqs. (3.23), that is, a superposition of the free waves (3.21), that satisfies the boundary conditions (3.19), should be found. As a result, one obtains the characteristic equation and normalized mode shapes as well as the orthogonality relation. Substitution of the dispersion (3.21) or (3.25) into the characteristic equation gives also the discrete spectrum of the natural frequencies. The characteristic equations and natural frequencies for several beams are presented in Table 2. The next step of the analysis is decomposition of the free or forced vibrations into the normal modes and determination of the unknown mode amplitudes from the initial conditions and external force.

Note that the orthogonality relation for the *BE* beam is the same as in (3.12). For the Timoshenko beam, it is more complicated and includes the weighted products of the displacements and slopes¹³:

$$\int_0^l [w_m(x)S w_n(x) + \theta_{ym}(x)I_y \theta_{yn}(x)] dx = \delta_{mn} \quad (3.26)$$

3.4 Nonsymmetric and Curved Beams

Uncoupled longitudinal, flexural, and torsional vibrations in a beam are possible only if it is straight and its cross section is symmetric with respect to planes xy and xz (Fig. 9). For arbitrary beam geometry, all these types of vibration are coupled and should be treated simultaneously.

Beam with a Nonsymmetric Cross Section

Engineering equations for coupled vibration of a thin straight uniform beam with a nonsymmetric cross section can be obtained with the help of the variational principle starting from the same assumptions that were made above for each type of motion separately. Namely, the beam cross section is assumed to have a hard undeformable contour in the yz plane (see Fig. 9) but has the ability to move in the x direction during torsion (i.e., depplanation is possible). Mathematically, it can be written as the following kinematics hypothesis:

$$\begin{aligned}u_x(x, y, z, t) &= u(x, t) + z\theta_y(x, t) \\ &\quad - y\theta_z(x, t) + \varphi(y, z)\theta'(x, t) \\ u_y(x, y, z, t) &= v(x, t) - z\theta(x, t) \\ u_z(x, y, z, t) &= w(x, t) + y\theta(x, t)\end{aligned}\quad (3.27)$$

Motion of a beam element dx is characterized by six independent quantities (or DOFs)—displacements u, v, w and angles $\theta, \theta_y, \theta_z$. Angles θ_y and θ_z do not coincide with $-w'$ and v' , thus, allowing additional shear deformation in bending (as in a Timoshenko

beam). Deplanation is described by the torsional function φ , which should be found from the boundary value problem as in Saint-Venant theory—see Eq. (3.15).

After writing the kinetic and potential energies and using the variational principle, one can obtain, from Eqs. (3.27), the set of six governing equations, each of the second order. There should be imposed six boundary conditions at each end. The equations as well as the expressions for the forces and moments at cross-section x can be found elsewhere.¹³

If the beam has arbitrary cross-section geometry, one of the equations, namely the equation of Bernoulli (3.4) of longitudinal vibration, is independent. Other five equations are coupled. If the beam cross section has a plane of symmetry, like in Π or T beams, flexural vibration in this plane becomes uncoupled and described by the Timoshenko equations (3.23). If the cross section has two planes of symmetry, like, for example, in a box beam, flexural vibration in both symmetry planes and torsional vibration are uncoupled and may be analyzed independently.

Curved Beams A curved beam is one more 1D model where various types of beam vibration may be coupled even if the cross section is symmetric. Geometrically, a curved beam is characterized by a local curvature and twist. In the general case of twisted beam, for example, in a helical spring, all the wave types are coupled including the longitudinal one. In a curved beam of symmetric cross section with no twist (the beam lies in a plane), for example, in a ring, there are two independent types of motion: coupled longitudinal-flexural vibration in the plane of the beam, and torsional-flexural vibration out of the plane. Governing equations for both types can be found in the literature.^{2,14}

4 CONTINUOUS TWO-DIMENSIONAL SYSTEMS

Two-dimensional (2D) continuous systems are models of engineering structures one dimension of which is small compared to two other dimensions and to the wavelength. A vibration field in a 2D system depends on time and two space coordinates. Examples of such systems are membranes, plates, shells, and other thin-walled structures. In this section, vibrations of the most used 2D systems—plates and cylindrical shells—are considered. Thin plates are models of flat structural elements. There are two independent types of plate vibrations—flexural and in-plane vibrations. Flexural vibrations of finite plates have comparatively low natural frequencies, they are easily excited (because of low stiffness) and play the key role in radiation of sound into environment. The in-plane vibrations of plates are “stiff” and radiate almost no sound, but they store a lot of the vibration energy and easily transport it to distant parts of elastic structures. Shells model curved thin 2D structural elements, like hulls, tanks, and the like. Generally, all types of vibration are coupled in shells due to the surface curvature.

4.1 Flexural Vibration of Thin Plates

Consider a uniform elastic plate of small thickness h made of an isotropic material with the Young's modulus E and Poisson's ratio ν . When the plate is bent, its layers near the convex surface are stretched, while the layers near the concave surface are compressed. In the middle, there is a plane, called the neutral plane, with no in-plane deformation. Let xy plane of Cartesian coordinates coincide with the neutral plane and axis z be perpendicular to it, so that $z = \pm h/2$ are the faces of the plate (Fig. 13).

The main assumption of the classical theory of flexural vibration of thin plates is the following: plane cross sections that are perpendicular to the middle plane before bending remain plane and perpendicular to the neutral plane after bending. It is equivalent to the kinematic hypothesis concerning distribution of the displacements u_x , u_y , and u_z over the plate:

$$\begin{aligned} u_x(x, y, z, t) &= -z \frac{\partial w}{\partial x} \\ u_y(x, y, z, t) &= -y \frac{\partial w}{\partial y} \\ u_z(x, y, z, t) &= w(x, y, t) \end{aligned} \quad (4.1)$$

where w the lateral displacement of the neutral plane. Besides, it is assumed that the normal lateral stress σ_{zz} is zero not only at the free planes $z = \pm h/2$ but also inside the plate.

Starting from Eq. (4.1) and Hook's law, one can compute strains and stresses, the kinetic and potential energy and obtain, with the help of the variational principle of the least action, the classical *equation of Germin–Lagrange* of flexural vibration on thin

Figure 13 Cartesian coordinates and the positive direction of the displacements, bending moments, and forces acting at the cross sections perpendicular to axes x and y .

plates¹⁵:

$$D\Delta\Delta w(x, y, t) + \rho h \ddot{w}(x, y, t) = p_z(x, y, t) \quad (4.2)$$

Here $D = Eh^3/12(1 - \nu^2)$ is the flexural stiffness, ρ is the mass density, p_z is the surface density of external forces, $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the Laplacian operator. The equation is of the fourth order with respect to the space coordinates, therefore two boundary conditions should be imposed at each edge that are similar to those of the flexurally vibrating beam. The expressions for the bending moments and effective shear forces are the following:

At the edge $x = \text{const.}$

$$\begin{aligned} M_{yx} &= -D \left(\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial y^2} \right) \\ F_{zx} &= -D \left[\frac{\partial^3 w}{\partial x^3} + (2 - \nu) \frac{\partial^3 w}{\partial x \partial y^2} \right] \end{aligned} \quad (4.3)$$

and at the edge $y = \text{const.}$

$$\begin{aligned} M_{xy} &= D \left(\frac{\partial^2 w}{\partial y^2} + \nu \frac{\partial^2 w}{\partial x^2} \right) \\ F_{zy} &= -D \left[\frac{\partial^3 w}{\partial y^3} + (2 - \nu) \frac{\partial^3 w}{\partial x^2 \partial y} \right] \end{aligned} \quad (4.4)$$

Double index notation for the moments and forces is adopted just in the same manner as for the stress components in theory of elasticity: The first index designates the component and the second index indicates the area under consideration. For example, M_{yx} is the y component of the moment of stresses at the area perpendicular to x axis—see Fig. 13.

The assumptions underlying the Germin–Lagrange equation (4.2) are identical to those of the Bernoulli–Euler equation (3.18). Moreover, these equations coincide if the wave motion on the plate does not depend on one of the space coordinates. Therefore, the general properties of flexural waves and vibration of plates are very similar to those of beams.

Consider a straight-crested time-harmonic flexural wave of frequency ω and complex displacement amplitude w_0 propagating at the angle ψ to the x axis:

$$w(x, y, t) = \text{Re} \{ w_0 \exp[ik(x \cos \psi + y \sin \psi) - i\omega t] \} \quad (4.5)$$

Substitution of this into Eq. (4.2) gives the dispersion equation

$$k^4 = k_p^4 = \frac{\rho h \omega^2}{D} \quad (4.6)$$

relating the wavenumber k to frequency ω . The equation has roots $\pm k_p, \pm ik_p$. Hence, there are two types of the plane waves in plates—propagating and

evanescent. The real-valued wavenumbers correspond to the propagating wave:

$$w_1 e^{ik_p(x \cos \psi + y \sin \psi) - i\omega t}$$

Its amplitude $|w_1|$ is constant everywhere on the plate. The imaginary-valued wavenumbers correspond to the evanescent wave:

$$w_2 e^{-k_p(x \cos \psi + y \sin \psi) - i\omega t}$$

Its amplitude changes along the plate. The steepest change takes place in the ψ direction, while along the straight line $\psi + \pi/2$ it remains constant. The graph of dispersion (4.6) is identical to curves BE in Fig. 12.

It follows from Eq. (4.6) that the phase velocity of the propagating wave is proportional to the square root of frequency. The group and energy velocities are twice the phase velocity, just as for the propagating flexural wave in a beam. This causes the distortion of the shape of disturbances that propagate on a plate.

Beside plane waves (4.5) with linear fronts, other types of the wave motion are possible on the plate as a 2D continuous system. Among them the axisymmetric waves with circular wavefronts are the most important. Such waves originate from local disturbances. In particular, if a time-harmonic force

$$p_z(x, y, t) = p_0 \delta(x - x_0) \delta(y - y_0) \exp(-i\omega t)$$

is applied to point (x_0, y_0) of an infinite plate, the flexural wave field is described by

$$\begin{aligned} w(x, y, t) &= p_0 g(x, y; x_0, y_0) = \frac{p_0}{8Dk_p^2} \\ &\times \left[H_0(k_p r) - \frac{2}{\pi} K_0(k_p r) \right] \\ r &= [(x - x_0)^2 + (y - y_0)^2]^{1/2} \end{aligned} \quad (4.7)$$

Here H_0 and K_0 are Hankel's and McDonald's cylindrical functions.⁶ The Green's function g of an infinite plate consists of the outgoing (propagating) circular wave $H_0(k_p r)$ and the circular evanescent wave described by the function $K_0(k_p r)$. When distance r is large ($k_p r \gg 1$), the response amplitude decreases as $r^{-1/2}$. For $r = 0$, Eq. (4.7) gives the input impedance of an infinite plate:

$$z_p = p_0 / \dot{w}(x_0, y_0, t) = 8\sqrt{Dm}$$

with $m = \rho h$. The impedance is real valued. Physically, this means that the power flow from the force source into the plate is pure active, and no reactive field component is excited in the plate.

The forced flexural vibrations of an infinite plate under the action of arbitrary harmonic force $p_z(x, y, t)$

can be computed with the help of Green's function (4.7):

$$w(x, y, t) = \iint_{\Omega} g(x, y; x_0, y_0) p_z(x_0, y_0, t) dx_0 dy_0 \quad (4.8)$$

where integration is performed over the area Ω where the external force is applied. If the force is not harmonic in time, the solution for the forced vibration can be obtained by integration of solution (4.8) over the frequency range.

As for the analysis of vibrations of finite plates, the general approach is the same as that for finite beams and NDOF systems. A finite plate of any geometry has an infinite countable number of the normal modes. The mode shapes are orthogonal and constitute a complete set functions, so that any free or forced vibrations of the finite plate can be decomposed into normal modes and found from the initial conditions and the prescribed force.

It is worth noting that the normal modes of most finite plates cannot be found analytically. For example, a rectangular plate admits the analytical solution only if a pair of opposite edges are simply supported [$w = M_{yx} = 0$ or $w = M_{xy} = 0$ —see Eqs. (4.3) and (4.4)] or sliding ($\partial w/\partial x = F_{zx} = 0$ or $\partial w/\partial y = F_{zy} = 0$). For a free plate ($M_{yx} = F_{zx} = 0$ and $M_{xy} = F_{zy} = 0$), clamped plate (displacements and slopes are zero at four edges) and for all other edge conditions analytical solutions are not found yet. However, the natural frequencies and mode shapes have been obtained numerically (by Ritz' method) for most practically important geometries.¹⁶

The range of validity of the Germin–Lagrange equation is restricted to low frequencies. Similar to the Bernoulli–Euler equation for beams, it is valid if the shear wavelength in the plate material is 10 times greater than the thickness h and the flexural wavelength is $6h$ or greater. In the literature, there are several attempts to improve the Germin–Lagrange equation. The best of them is the theory of Uflyand¹⁷ and Mindlin.¹⁸ It relates to the classical theory of Germin–Lagrange just as the Timoshenko theory of beams relates to the Bernoulli–Euler theory: The shear deformations and rotatory inertia are taken into account. As a result, the frequency range of its validity is an order of magnitude wider than that of the classical equation (4.2).

4.2 In-Plane Vibration of Plates

In-plane waves and vibration of a plate are symmetric with respect to the midplane and independent from its flexural (antisymmetric) vibrations. In the engineering theory of in-plane vibrations, which is outlined in this subsection, it is assumed that, due to small h compared to the shear wavelength, all the in-plane displacement and stresses are uniform across the thickness and that the lateral stresses are zero not only at the faces but also inside the plate:

$$\sigma_{xz} = \sigma_{yz} = \sigma_{zz} = 0 \quad (4.9)$$

Mathematically, these assumptions can be written as

$$\begin{aligned} u_x(x, y, z, t) &= u(x, y, t) \\ u_y(x, y, z, t) &= v(x, y, t) \\ u_z(x, y, z, t) &= -\frac{vz}{1-\nu} \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) \end{aligned} \quad (4.10)$$

Computing from (4.9) and (4.10) the kinetic and potential energies, one can obtain, using the variational principle of the least action, the following equations¹⁵:

$$\begin{aligned} K_l \frac{\partial^2 u}{\partial x^2} + K_t \frac{\partial^2 u}{\partial y^2} + \Delta K \frac{\partial^2 v}{\partial x \partial y} - \rho h \ddot{u} &= -p_x(x, y, t) \\ K_t \frac{\partial^2 v}{\partial x^2} + K_l \frac{\partial^2 v}{\partial y^2} + \Delta K \frac{\partial^2 u}{\partial x \partial y} - \rho h \ddot{v} &= -p_y(x, y, t) \end{aligned} \quad (4.11)$$

where u and v are the displacements in x and y directions (see Fig. 13); the thin plate longitudinal and shear stiffnesses are equal to

$$\begin{aligned} K_l &= \frac{Eh}{1-\nu^2} \quad K_t = Gh = \frac{Eh}{2(1+\nu)} \\ \Delta K &= K_l - K_t = \frac{Eh}{2(1-\nu)} \end{aligned} \quad (4.12)$$

and p_x, p_y are the surface densities of external forces. Two boundary conditions should be prescribed at each edge, and the following force–displacement relations take place:

$$\begin{aligned} F_{xx} &= K_l \left(\frac{\partial u}{\partial x} + \nu \frac{\partial v}{\partial y} \right) \\ F_{xy} = F_{yx} &= K_t \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \\ F_{yy} &= K_l \left(\frac{\partial v}{\partial y} + \nu \frac{\partial u}{\partial x} \right) \end{aligned} \quad (4.13)$$

Elementary in-plane wave motions have the form of a time-harmonic plane wave propagating at angle ψ to x axis:

$$\begin{bmatrix} u(x, y, t) \\ v(x, y, t) \end{bmatrix} = \begin{bmatrix} u \\ v \end{bmatrix} \exp[ik(x \cos \psi + y \sin \psi) - i\omega t]$$

It satisfies homogeneous equations (4.11) and the following dispersion equation:

$$(k^2 - k_l^2)(k^2 - k_t^2) = 0 \quad (4.14)$$

where $k_l = \omega/c_l$, $k_t = \omega/c_t$. It is seen that two types of plane waves exist on the plate. The first is the longitudinal wave

$$A_l \begin{bmatrix} \cos \psi \\ \sin \psi \end{bmatrix} \exp[ik_l(x \cos \psi + y \sin \psi) - i\omega t]$$

that propagates with the phase velocity $c_l = (K_l/\rho h)^{1/2}$ in which the plate particles move in the direction of wave propagation. The second is the shear wave

$$A_t \begin{bmatrix} -\sin \psi \\ \cos \psi \end{bmatrix} \exp[ik_t(x \cos \psi + y \sin \psi) - i\omega t]$$

that propagates with the phase velocity $c_t = (K_t/\rho h)^{1/2}$ in which the plate particles displacements are perpendicular to the direction of wave propagation. Both waves are propagating ones at all frequencies. Their group and energy velocities are equal to the phase velocity and do not depend on frequency. For that reason, any in-plane disturbance propagates along the plate without distortion.

As in case of flexural vibration, problems of free or forced in-plane vibration of a finite plate are seldom solvable analytically. For example, for rectangular plates analytical solutions exist only if at a pair of the opposite edges the so-called mixed boundary conditions are prescribed (the mixed conditions at an edge normal to x axis are $F_{xx} = v = 0$ or $F_{yx} = u = 0$; at an edge normal to the y axis they are $F_{xy} = v = 0$ or $F_{yy} = u = 0$). For all other boundary conditions, the natural frequencies and modal shapes should be computed numerically.¹⁶

The frequency range of validity of Eqs. (4.11) is rather wide—the same as that of the Bernoulli equation (3.4) of longitudinal vibration in beams (see Fig. 10). They are valid even if the shear wavelength is comparable with the plate thickness h .

4.3 Vibration of Shells

Shells are models of curved thin-walled elements of engineering structures such as ship hulls, fuselages, cisterns, pipes, and the like. Most theories of shell vibration are based on Kirchhoff–Love's hypothesis that is very similar to that of flat plates. Since flexural and in-plane vibrations are coupled in shells, the corresponding engineering equations are rather complicated even in the simplest cases: The total order of the space derivatives is eight. In this subsection, waves and vibration of a uniform closed circular cylindrical shell are briefly documented. Results of more detailed analysis of vibration of this and other shells can be found elsewhere.¹⁹

According to Kirchhoff–Love's hypothesis, the shell thickness h is small compared to the shear wavelength, to other two dimensions, and to the smaller radius of curvature. Therefore, the transverse normal stresses are assumed zero, and plane cross sections perpendicular to the undeformed middle surface remain plane and perpendicular to the deformed middle surface. These may be written as a kinematic hypothesis, which is a combination of hypotheses (4.1) and (4.10). After computing, with the help of Hook's law and surface theory relations, the strains and stresses, kinetic and potential energy, one can obtain from the variational principle the following

Figure 14 Circular cylindrical shell and the positive direction of the displacements, forces, and moments at x cross section.

engineering equations known as *Donnell–Mushtari equations*¹⁹:

$$\rho h \ddot{\mathbf{u}}(x, s, t) - \mathbf{L} \mathbf{u}(x, s, t) = \mathbf{q}(x, s, t) \quad (4.15)$$

where $s = a\theta$ (see Fig. 14), a and h are the radius and thickness of the shell, $\mathbf{u} = [u, v, w]^T$ is the displacement vector, \mathbf{q} is the vector of the external force densities, \mathbf{L} is the 3×3 matrix of the differential operators:

$$\begin{aligned} L_{11} &= K_l \frac{\partial^2}{\partial x^2} + K_t \frac{\partial^2}{\partial s^2} \\ L_{12} &= L_{21} = \Delta K \frac{\partial^2}{\partial x \partial s} \\ L_{13} &= -L_{31} = \nu K_l \frac{1}{a} \frac{\partial}{\partial x} \\ L_{22} &= K_t \frac{\partial^2}{\partial x^2} + K_l \frac{\partial^2}{\partial s^2} \\ L_{23} &= -L_{32} = K_l \frac{1}{a} \frac{\partial}{\partial s} \\ L_{33} &= K_l \frac{1}{a^2} + D \Delta^2 \end{aligned} \quad (4.16)$$

Here K_l , K_t , and D are the longitudinal, shear, and flexural thin-plate stiffnesses—see Eqs. (4.2) and (4.12), $\Delta = \partial^2/\partial x^2 + \partial^2/\partial s^2$. Four boundary conditions should be prescribed at each edge. The

forces and moments at cross-section $x = \text{const.}$ are

$$\begin{aligned} F_{xx} &= -K_l \left(\frac{\partial u}{\partial x} + \nu \frac{\partial v}{\partial s} + \nu \frac{w}{a} \right) \\ F_{sx} &= -K_t \left(\frac{\partial u}{\partial s} + \frac{\partial v}{\partial x} \right) \\ F_{rx} &= -D \left[\frac{\partial^3 w}{\partial x^3} + (2 - \nu) \frac{\partial^3 w}{\partial x \partial s^2} \right] \\ M_{sx} &= -D \left(\frac{\partial^2 w}{\partial x^2} + \nu \frac{\partial^2 w}{\partial s^2} \right) \end{aligned} \quad (4.17)$$

Among a large number of thin-shell engineering theories, Eqs. (4.15) are the simplest that describe coupled flexural and in-plane vibration. When radius a of the shell tends to infinity, these two types of vibration become uncoupled: Eqs. (4.15) reduce to Eqs. (4.11) for in-plane vibration and to the classical Germin–Lagrange equation (4.2). The matrix operator \mathbf{L} in (4.15) is self-adjoint, and, hence, the reciprocal Maxwell–Betti theorem is valid in the Donnell–Mushtari shell.

From the wave theory point of view, a thin cylindrical shell is a 2D solid waveguide.⁹ At each frequency, there exist, in such a waveguide, an infinite (countable) number of the normal modes of the form

$$\mathbf{u}_m(x, s, t) = \mathbf{u}_m(s) \exp(ikx - i\omega t) \quad (4.18)$$

where k and $\mathbf{u}_m(s)$ are the propagation constant and shape of the normal mode, $m = 0, 1, 2, \dots$. For a closed cylindrical shell, the shape function $\mathbf{u}_m(s)$ is a periodic function of s with period $2\pi a$ and, hence, can be decomposed into the Fourier series. For circumferential number m the shapes are $[u_m \cos \psi_m, v_m \sin \psi_m, w_m \cos \psi_m]^T$ or $[u_m \sin \psi_m, -v_m \cos \psi_m, w_m \sin \psi_m]^T$, $\psi_m = ms/a$; u_m, v_m, w_m are the complex amplitudes of the displacement components. Substitution of (4.18) into Eq. (4.15) leads to the dispersion relation in the form of a polynomial of the fourth order with respect to k^2 . Hence, for each circumferential number m , there are four root pairs $\pm k_j$, $j = 1 \div 4$, that correspond to four types of the normal modes.

Consider axisymmetric normal modes, $m = 0$. The real and imaginary branches of dispersion are shown in Fig. 15. One real-valued root of the dispersion equation is $k = \pm k_t$ (curve 2). It corresponds to the propagating torsional wave. Another real-valued root at low frequencies is $k = \pm k_l$. It corresponds to the longitudinal propagating wave. The remaining low-frequency roots of the dispersion equation are complex and correspond to complex evanescent waves. The frequency rf for which $k_l a = f/\text{rf} = 1$ is called *the ring frequency*. At this frequency, the infinite shell is pulsating in the radial direction while the tangential and axial displacements are zero. Near the ring frequency, two complex waves transform into

Figure 15 First four real and imaginary branches of dispersion of the axisymmetric ($m = 0$) normal modes of the Donnell–Mushtari closed cylindrical shell: $h/a = 0.02$; frequency is normalized with the ring frequency.

one propagating wave and one evanescent wave. At high frequencies, the four shell normal waves are indiscernible from two flexural and two in-plane waves of the flat plate.

Very similar behavior demonstrates dispersion of normal modes with higher circumferential numbers m . For $m \geq 2$, all low-frequency roots of the dispersion equation are complex, and the corresponding normal modes are complex evanescent waves. At higher frequencies, they transform into imaginary evanescent and propagating waves. And at very high frequencies the dispersion of the shell normal modes tends to dispersion of the plate waves (4.6) and (4.14).

Analysis of finite shell vibrations is very similar to that of other elastic systems: Free or forced vibrations are decomposed in the normal modes. The natural frequencies and mode shapes are obtained from solution of Eqs. (4.15) with four boundary conditions at each edge. The most simple is the case of the so-called Navier conditions at both edges $x = 0, l$. These are mixed conditions [e.g., $M_{sx} = w = F_{xx} = v = 0$ —see Eq. (4.17)]. The shell normal modes do not interact at such edges reflecting independently. Finite shells with other boundary conditions are analyzed numerically.¹⁹

The range of validity of the Donnell–Mushtari theory, as well as of other theories based on the Kirchhoff–Love hypothesis, is restricted to low frequencies. Their energy errors are estimated as $\max\{(kh)^2, h/a\}$.

The theory of Donnell–Mushtari admits one important simplification. When a shell is very thin and, hence, very soft in bending, the flexural stiffness may be neglected, $D = 0$, and Eqs. (4.15) become of the fourth order. This case corresponds to *the membrane theory*. On the contrary, when a shell is thick, more

complicated theories are needed to take into account the additional shear deformations and rotatory inertia (as in the Timoshenko beam theory) as well as other effects.^{14,19}

CHAPTER 13

RANDOM VIBRATION

David E. Newland
Engineering Department
Cambridge University
Cambridge, United Kingdom

1 INTRODUCTION

Random vibration combines the statistical ideas of random process analysis with the dynamical equations of applied mechanics. The theoretical background is substantial, but its essence lies in only a few fundamental principles. Familiarity with these principles allows the solution of practical vibration problems. Random vibration includes elements of probability theory, correlation analysis, spectral analysis, and linear system theory. Also, some knowledge of the response of time-varying and nonlinear systems is helpful.

2 SUMMARY OF STATISTICAL CONCEPTS

Random vibration theory seeks to provide statistical information about the severity and properties of vibration that is irregular and does not have the repetitive properties of deterministic (nonrandom) harmonic motion. This statistical information is represented by probability distributions.

2.1 First-Order Probability Distributions

Probability distributions describe how the values of a random variable are distributed. If $p(x)$ is the *probability density function* for a random variable x , then $p(x)dx$ is the probability that the value of x at any chosen time will lie in the range x to $x + dx$. For example, if $p(x)dx = .01$, then there is a 1 in 100 chance that the value of x at the selected time will lie in the chosen band x to $x + dx$. Since there must be some value for x between $-\infty$ and $+\infty$, it follows that

$$\int_{-\infty}^{\infty} p(x) dx = 1 \quad (1)$$

The *average (or mean) value* of x is expressed as $E[x]$ and is given by the equation

$$E[x] = \int_{-\infty}^{\infty} x p(x) dx \quad (2)$$

The *ensemble average* symbol E indicates that the average has been calculated for infinitely many similar situations. The idea is that an experiment is being conducted many times, and that the measured value is recorded simultaneously for all the ongoing similar experiments. This is different from sampling the same experiment many times in succession to calculate a *sample average*. Only if the random process is

stationary and *ergodic* will the sample average be the same as the ensemble average.

A process is said to be *stationary* if its statistical descriptors do not change with time. It is also *ergodic* if every sample function has the same sample averages.

2.2 Higher-Order Probability Distributions

This idea of distributions is extended to cases when there are more than one random variable, leading to the concept of *second-order probability density functions*, $p(x_1, x_2)$. Corresponding to (1), these have to be normalized so that

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} p(x_1, x_2) dx_1 dx_2 = 1 \quad (3)$$

and the ensemble average of the product of random variables $x_1 x_2$ is then given by

$$E[x_1 x_2] = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} x_1 x_2 p(x_1, x_2) dx_1 dx_2 \quad (4)$$

If all the higher-order probability density functions $p(x_1, x_2, x_3, \dots)$ of a random process are known, then its statistical description is complete. Of course, they never are known because an infinite number of measurements would be needed to measure them, but it is often assumed that various simplified expressions may be used to define the *probability distribution* of a random process.

2.3 Commonly Assumed Probability Distributions

The most common assumption is that a random variable has a normal or *Gaussian distribution* (Fig. 1). Then $p(x)$ has the familiar bell-shaped curve, and there are similar elliptical bell shapes in higher dimensions. Equations for the Gaussian bell are given, for example, in Newland.¹

A second common assumption is the *Rayleigh distribution* (Fig. 2a). This is often used to describe how peaks are distributed (every peak is assumed to have an amplitude somewhere between zero and infinity, therefore $p(x)$ is zero for $x < 0$).

A more general but similar distribution is defined by the *Weibull function* (Fig. 2b). This has been found to represent some experimental situations quite well and is often used. Equations for Rayleigh and Weibull distributions are also given in Newland.¹

Figure 1 (a) First-order Gaussian probability density function and (b) second-order Gaussian probability surface.

2.4 Autocorrelation and Spectral Density

In order to describe the statistical frequency of random processes, the concept of *spectral density* is used. The idea is that, although a random signal will have no harmonics (as a periodic signal would have), its energy will be distributed continuously across the frequency spectrum from very low or zero frequency to very high frequencies. Because a stationary random signal has no beginning or ending (in theory), its Fourier transform does not exist. But if the signal is averaged to compute its *autocorrelation function* $R_{xx}(\tau)$ defined by

$$R_{xx}(\tau) = E[x(t)x(t + \tau)] \quad (5)$$

this function decays to zero for τ large (Fig. 3).

The graph becomes asymptotic to the square of the mean value m^2 and is confined between upper and lower limits $m^2 \pm \sigma^2$ where σ is the standard deviation defined by

$$\sigma^2 = E[x^2] - m^2 \quad (6)$$

and m is the mean value defined by

$$m = E[x] \quad (7)$$

The Fourier transform of $R_{xx}(\tau)$ is the mean-square *spectral density* of the random process $x(t)$. Its formal

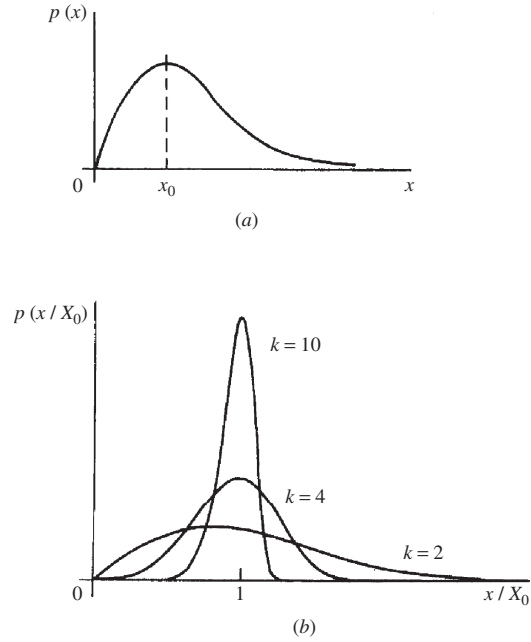

Figure 2 (a) Rayleigh probability density function and (b) Weibull probability density functions (different choices of the parameter k are possible).

definition is

$$S_{xx}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} R_{xx}(\tau) e^{-i\omega\tau} d\tau \quad (8)$$

In this formula ω is the angular frequency (units of radians/second) and, to allow the complex exponential representation to be used, must run from minus infinity to plus infinity. However $S_{xx}(\omega)$ is symmetrical about the $\omega = 0$ position (Fig. 4).

It can be shown that $S_{xx}(\omega)$ is always real and positive and the area under the graph in Fig. 4 is numerically equal to the signal's mean-square value $E[x^2]$ (see Newland¹).

Figure 3 Typical autocorrelation function for a stationary random process.

Figure 4 Typical spectral density function plotted as a function of angular frequency.

By computing the inverse Fourier transform of $S_{xx}(\omega)$, the autocorrelation function $R_{xx}(\tau)$ can be recovered.

2.5 Cross Correlation and Cross Spectral Density

Similar relationships hold for cross-correlation functions in which sample functions from two different random processes are averaged, and these lead to the theory of *cross correlation* and the *cross-spectral density function* $S_{xy}(\omega)$ where the subscripts x and y indicate that samples from two different random variables $x(t)$ and $y(t)$ have been processed. A selection of relevant source literature is included in Refs. 1 to 9.

There are specialist *fast Fourier transform (FFT)* algorithms for computing spectral densities. These are routinely used for practical calculations (see Newland,¹ Press et al.,¹⁰ and Chapter 42 of this handbook).

3 SUMMARY OF APPLIED MECHANICS CONCEPTS

Applied mechanics theory (see, e.g., Newland¹¹) provides the system response properties that relate response and excitation. Therefore, applied mechanics theory allows the input–output properties of dynamical systems to be calculated and provides the connection between random vibration excitation and the random vibration response of deterministic systems.

3.1 Frequency Response Function

For time-invariant linear systems with an input $x(t)$ and a response $y(t)$, if the input is a harmonic forcing function represented by the complex exponential function

$$x(t) = e^{i\omega t} \quad (9)$$

the response is, after starting transients have decayed to zero,

$$y(t) = H(i\omega)e^{i\omega t} \quad (10)$$

where $H(i\omega)$ is the complex *frequency response function* for the system.

3.2 Impulse Response Function

Corresponding to the frequency response function is its (inverse) Fourier transform

$$h(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} H(i\omega)e^{i\omega t} d\omega \quad (11)$$

which is called the *impulse response function*. It can be shown (see Newland¹) that $h(t)$ describes the response of the same system when a unit impulsive hammer blow is applied to the input with the system initially quiescent.

4 INPUT–OUTPUT RESPONSE RELATIONSHIPS FOR LINEAR SYSTEMS

4.1 Single-Input, Single-Output (SISO) Systems

There are two key input–output relationships.¹ The first relates the *average value* of the response of a linear time-invariant system when excited by stationary random vibration to the average value of the excitation. If $x(t)$ is the input (or excitation) with ensemble average $E[x]$ and $y(t)$ is the output (or response) with ensemble average $E[y]$, and if $H(i0)$ is the (real) value of the frequency response function $H(i\omega)$ at zero frequency, $\omega = 0$, then

$$E[y] = H(i0)E[x] \quad (12)$$

For linear systems, the mean level of excitation is transmitted as if there were no superimposed random fluctuations. Since, for many systems, there is no response at zero frequency, so that $H(i0) = 0$, it follows that the mean level of the response is zero whether the excitation has a zero mean or not.

The second and key relationship is between the *spectral densities*. The input spectral density $S_{xx}(\omega)$ and the output spectral density $S_{yy}(\omega)$ are connected by the well-known equation

$$S_{yy}(\omega) = |H(i\omega)|^2 S_{xx}(\omega) \quad (13)$$

This says that the spectral density of the output can be obtained from the spectral density of the input by multiplying by the magnitude of the frequency response function squared. Of course, all the functions are evaluated at the same frequency ω . It is assumed that the system is linear and time invariant and that it is excited by random vibration whose statistical properties are stationary.

4.2 Multiple Input, Multiple Output (MIMO) Systems

For Eq. (13), there is only one input and one output. For many practical systems there are many inputs and several outputs of interest. There is a corresponding result that relates the spectral density of each output to the spectral densities of all the inputs and the cross-spectral densities of each pair of inputs (for every input paired with every other input). The result is conceptually similar to (13) and is usually expressed in matrix form^{1,8}:

$$S_{yy}(\omega) = H^*(\omega)S_{xx}(\omega)H^T(\omega) \quad (14)$$

where now the functions are matrices. For example, the function in the m th row and n th column of $S_{yy}(\omega)$

is the cross-spectral density between the m th and n th outputs. The asterisk in (14) denotes the complex conjugate of $H(\omega)$ and the T denotes the transposition of $H(\omega)$.

There are similar matrix relationships between all the input and output statistics for time-invariant, linear systems subjected to stationary excitation. There is an extension for the general case of continuous systems subjected to distributed excitation, which is varying randomly in space as well as time, and simplifications when modal analysis can be carried out and results expressed in terms of the response of normal modes. These are covered in the literature, for which a representative sample of relevant reference sources is given in the attached list of references.

5 INPUT-OUTPUT RESPONSE RELATIONSHIPS FOR OTHER SYSTEMS

5.1 General

The theoretical development is much less cut-and-dried when the system that is subjected to random excitation is a nonlinear system or, alternatively, is a linear system with parametric excitation.¹² The responses of such systems have not yet been reduced to generally applicable results. Problems are usually solved by approximate methods. Although, in principle, exact solutions for the response of any dynamical system (linear or nonlinear) subjected to white Gaussian excitation can be obtained from the theory of *continuous Markov processes*, exact solutions are rare, and approximate methods have to be used to find solutions. This puts Markov analysis on the same footing as other approximate methods. *Perturbation techniques* and *statistical linearization* are two approximate methods that have been widely used in theoretical analysis.

5.2 Perturbation Techniques

The basic idea is to expand the solution as a power series in terms of a small scaling parameter. For example, the solution of the weakly nonlinear system

$$\ddot{y} + \eta \dot{y} + \omega^2 y + \varepsilon f(y, \dot{y}) = x(t) \quad (15)$$

where $|\varepsilon| \ll 1$, is assumed to have the form

$$y(t) = y_0(t) + \varepsilon y_1(t) + \varepsilon^2 y_2(t) + \cdots \quad (16)$$

After substituting (16) into (15) and collecting terms, the coefficients of like powers of ε are then set to zero. This leads to a hierarchy of linear second-order equations that can be solved sequentially by linear theory.

Using these results, it is possible to calculate approximations for $R_{yy}(\tau)$ from (5) and then for the spectral density $S_{yy}(\omega)$ from the transform equation (8). Because of their complexity, in practice results have generally been obtained to first-order accuracy only. The method can be extended to multi-degree-of-freedom systems, but there may then be

huge algebraic complexity. A general proof of convergence is not currently available.

5.3 Statistical Linearization

This method involves replacing the governing set of differential equations by a set of linear differential equations that are “equivalent” in some way. The parameters of the equivalent system are obtained by minimizing the equation difference, calculated as follows. If a linear system

$$\ddot{y} + \eta_e \dot{y} + \omega_e^2 y = x(t) \quad (17)$$

is intended to be equivalent to the nonlinear system (15), the equation difference is obtained by subtracting one equation from the other to obtain

$$e(y, \dot{y}) = \varepsilon f(y, \dot{y}) + (\eta - \eta_e) \dot{y} + (\omega^2 - \omega_e^2) y \quad (18)$$

where η_e and ω_e^2 are unknown parameters. They are chosen so as to minimize the mean square of the equation difference $e(y, \dot{y})$.

This requires the probability structure of $y(t)$ and $\dot{y}(t)$ to be known, which usually it is not. Instead it is assumed that the response variables have a Gaussian distribution. Even if $x(t)$ is not Gaussian, it has been found that this will be approximately true for lightly damped systems.

There has been considerable research on the statistical linearization method,^{13,14} and it has been used to analyze many practical response problems, including problems in earthquake engineering with hysteretic damping that occurs due to slipping or yielding.

5.4 Monte Carlo Simulation

This is the direct approach of numerical simulation. Random excitation with the required properties is generated artificially, and the response it causes is found by numerically integrating the equations of motion. Provided that a sufficiently large number of numerical experiments are conducted by generating new realizations of the excitation and integrating its response, an ensemble of sample functions is created from which response statistics can be obtained by averaging across the ensemble. This permits the statistics of nonstationary processes to be estimated by averaging data from several hundred numerically generated sample functions.

For numerical predictions, either Monte Carlo methods, or the analytical procedures developed by Bendat¹⁵ are generally used.

6 APPLICATIONS OF RANDOM VIBRATION THEORY

6.1 General

For the wide class of dynamical systems that can be modeled by linear theory, it is possible to calculate all the required statistical properties of the response, provided that sufficient statistical detail is given about the

excitation. In practice, far-ranging assumptions about the excitation are often made, but it is nevertheless of great practical importance to be able to calculate statistical response data and there are many applications.

6.2 Properties of Narrow-Band Random Processes

When a strongly resonant system responds to broadband random excitation, its response spectral density falls mainly in a narrow band of frequencies close to the resonant frequency. Since this output is derived by filtering a broadband process, many nearly independent events contribute to it. Therefore, on account of the central limit theorem,⁴ the probability distribution of a narrow-band response process approaches that of a Gaussian distribution even if the excitation is not Gaussian.

This is an important result. If the response spectral density of a narrow-band process $S_{yy}(\omega)$ is known, because it is (assumed) to be Gaussian, all the other response statistics can be derived from $S_{yy}(\omega)$.

For any stationary random process $y(t)$, it can be shown¹ that the response displacement $y(t)$ and response velocity $\dot{y}(t)$ are uncorrelated, so that their joint probability density function $p(y, \dot{y})$ can be expressed as the product of the two first-order probability density functions $p(y)$ and $p(\dot{y})$ for $y(t)$ and $\dot{y}(t)$ so that

$$p(y, \dot{y}) = p(y)p(\dot{y}) \quad (19)$$

This is important in the development of crossing analysis (see below).

6.3 Crossing Analysis

Figure 5 shows a sample function from a stationary narrow-band random process.

The ensemble average number of up-crossings (crossings with positive slope) of the level $y = a$ in time T will be proportional to T , and this leads to the concept of an average frequency for up-crossings, which is usually denoted by the symbol $v^+(a)$. For a linear system subjected to Gaussian excitation with zero mean, it can be shown that $v^+(a)$ is given by

$$v^+(a = 0) = \frac{1}{2\pi} \left[\frac{\int_{-\infty}^{\infty} \omega^2 S_{yy}(\omega) d\omega}{\int_{-\infty}^{\infty} S_{yy}(\omega) d\omega} \right]^{1/2} \quad (20)$$

Figure 5 Up-crossings of a sample function from a narrow-band process $y(t)$.

This is the ensemble average frequency of zero crossings for the $y(t)$ process. It is only the same as the average frequency along the time axis if the process is ergodic.

6.4 Distribution of Peaks

For a narrow-band process that has one positive peak for every zero crossing, the proportion of cycles whose peaks exceed $y = a$ is $v^+(a)/v^+(0)$. This is the probability that any peak chosen at random exceeds a . For Gaussian processes, it leads to the result that¹

$$p_p(a) = \frac{a}{\sigma_y^2} \exp\left(-\frac{a^2}{2\sigma_y^2}\right) \quad (21)$$

for $a \geq 0$, which is the Rayleigh distribution shown in Fig. 2a.

This result depends on the assumption that there is only one positive peak for each zero crossing. An expression can be calculated for the frequency of maxima of a narrow-band process, and this assumption can only be valid if the frequency of zero crossings and the frequency of maxima are the same. It turns out that they are the same only if the spectral bandwidth is vanishingly small, which of course it never is. So in practical cases, irregularities in the narrow-band waveform in Fig. 5 give rise to additional local peaks not represented by the Rayleigh distribution (21). A more general (and more complicated) expression for the distribution of peaks can be calculated that incorporates a factor that is the ratio of the average number of zero crossings divided by the average number of peaks. For a broadband random process, there are many peaks for each zero crossing. In the limiting case, the distribution of peaks is just a Gaussian distribution that is the same as the (assumed) Gaussian amplitude distribution.

6.5 Envelope Properties

The envelope $A(t)$ of a random process $y(t)$ may be defined in various different ways. For each sample function it consists of a smoothly varying pair of curves that just touches the extremes of the sample function but never crosses them. The differences in definition revolve around where the envelope touches the sample function. This can be at the tips of the peaks or slightly to one side of each peak to give greater smoothness to the envelope.

One common definition is to say that the envelope is the pair of curves $A(t)$ and $-A(t)$ given by

$$A^2(t) = y^2(t) + \frac{\dot{y}^2(t)}{v^+(0)^2} \quad (22)$$

where $v^+(0)$ is the average frequency of zero crossings of the $y(t)$ process.

When $y(t)$ is stationary and Gaussian, it can then be shown that this definition leads to the following

Figure 6 Envelope of a sample function from a narrow-band process $y(t)$.

envelope probability distribution:

$$p(A) = \frac{A}{\sigma_y^2} \exp\left(-\frac{A^2}{2\sigma_y^2}\right) \quad A \geq 0 \quad (23)$$

which is the same as the probability distribution for the peaks of a narrow band, stationary, Gaussian process (21). However, the two distributions differ if the process $y(t)$ is not both narrow and Gaussian.

6.6 Clumping of Peaks

The response of a narrow-band random process is characterized by a slowly varying envelope, so that peaks occur in clumps. Each clump of peaks greater than a begins and ends by its envelope crossing the level $y = a$ (Fig. 6). For a process with a very narrow bandwidth, the envelope is very flat and clumps of peaks become very long.

It is possible to work out an expression for the average number of peaks per clump of peaks exceeding level $y = a$, subject to necessary simplifying assumptions. This is important in some practical applications, for example, fatigue and endurance calculations, when a clump of large peaks can do a lot of harm if it occurs early in the duration of loading.

6.7 Nonstationary Processes

One assumption that is inherent in the above results is that of stationarity. The statistical properties of the random process, whatever it is, are assumed not to change with time. When this assumption cannot be made, the analysis becomes much more difficult. A full methodology is given in Piersol and Bendat.⁷

If the probability of a nonstationary process $y(t)$ remains Gaussian as it evolves, it can be shown that its peak distribution is close to a Weibull distribution. The properties of its envelope can also be calculated.⁸

6.8 First-Passage Time

The first-passage time for $y(t)$ is the time at which $y(t)$ first crosses a chosen level $y = a$ when time is measured forward from some specified starting point. A stationary random process has no beginning or ending, but the idea that a stationary process can be “turned on” at $t = 0$ is used to predict the time of failure if this occurs when $y(t)$ first crosses the $y = a$ level.

Subject to important simplifying assumptions, the probability density function for first-passage time is

$$p(T) = v^+(a) \exp(-v^+(a)T) \quad T > 0 \quad (24)$$

from which the mean and variance of the first-passage time can be calculated to be

$$E[T] = \frac{1}{v^+(a)} \quad \text{and} \quad \text{var}[T] = \frac{1}{[v^+(a)]^2} \quad (25)$$

A general exact solution for the first-passage problem has not yet been found. The above results are only accurate for crossings randomly distributed along the time axis. Because of clumping, the intervals between clumps will be longer than the average spacing between crossings and the probability of a first-passage excursion will, therefore, be less than indicated by the above theory.

6.9 Fatigue Failure under Random Vibration

The calculation of fatigue damage accumulation is complex and there are various different models. One approach is to assume that individual cycles of stress can be identified and that each stress cycle advances a fatigue crack. When the crack reaches a critical size, failure occurs. One cycle of stress of amplitude S is assumed to generate $1/N(S)$ of the damage needed to cause failure.

For a stationary, narrow-band random process with average frequency $v^+(0)$, the number of cycles in time T will be $v^+(0)T$. If the probability density for the distribution of peaks is $p_p(S)$, then the average number of stress cycles in the range S to $S + dS$ will be $v^+(0)T p_p(S) dS$. The damage done by this number of stress cycles is

$$v^+(0)T p_p(S) dS \frac{1}{N(S)} \quad (26)$$

and so the average damage $D(T)$ done by all stress cycles together will be

$$E[D(T)] = v^+(0)T \int_0^\infty \frac{1}{N(S)} p_p(S) dS \quad (27)$$

Failure is assumed to occur when the accumulated damage $D(T)$ is equal to one.

The variance of the accumulated fatigue damage can also be calculated, again subject to simplifying assumptions.² It can be shown that, when there is a substantially narrow-band response, an estimate of the average time to failure can be made by assuming that this is the value of T when $E[D(T)] = 1$.

It has been found that (27) tends to overestimate fatigue life, sometimes by an order of magnitude, even for narrow-band processes. Generally, “peak counting” procedures have been found more useful for numerical predictions (see, e.g., Ref. 16).

Of course the practical difficulty is that, although good statistical calculations can be made, the fracture model is highly idealistic and may not represent what really happens adequately.

CHAPTER 14

RESPONSE OF SYSTEMS TO SHOCK

Charles Robert Welch and Robert M. Ebeling
Information Technology Laboratory
U.S. Army Engineer Research and Development Center
Vicksburg, Mississippi

1 INTRODUCTION

Shock loading is a frequent experience. The slamming shut of a door or window, the dropping of a package and its impact onto a hard surface, and the response of a car suspension system to a pothole are everyday examples of shock loading. Less common examples include the explosive loading of structures, the impact of water waves onto piers and marine structures, and the response of targets to high-velocity projectiles.

This chapter treats the response of mechanical systems to shock loading. The nature of shock loading is discussed, and references are provided that give details of some common and uncommon loading functions, such as impact and explosion-induced air blast and water shock. The mechanical systems are simplified as single-degree-of-freedom (SDOF), spring-mass-dashpot systems. A unified treatment is provided that treats the response of these SDOF systems to a combination of directly applied forces and to motions of their supporting bases. SDOF systems fall naturally into one of four categories: undamped, underdamped, critically damped, and overdamped. We describe these categories and then treat the response of undamped and underdamped systems to several loading situations through the use of general methods including the Duhamel integral, Laplace transforms, and shock spectra methods. Lastly, examples of shock testing methods and equipment are discussed.

2 NATURE OF SHOCK LOADING AND ASSOCIATED REFERENCES

Shock loading occurs whenever a mechanical system is loaded faster than it can respond. Shock loading is a matter of degree. For loading rates slower than the system's response the system responds to the time-dependent details of the load, but as the loading rate becomes faster than the system's ability to respond, the system's response gradually changes to one that depends on only the total time integral, or impulse, of the loading history.

Undamped and underdamped mechanical systems respond in an oscillatory fashion to transient loads. Associated with this oscillatory behavior is a characteristic natural frequency. Another way of describing

shock loading is that, as the frequency content of the loading history increases beyond the natural frequency of the system, the system's response becomes more impulsive, until in the limit the response becomes pure shock response.

There is an equivalency between accelerating the base to which the SDOF system is attached and applying a force directly to the responding SDOF mass. Hence, shock loading also occurs as the frequency content of the base acceleration exceeds the system's natural frequency.

The quintessential historic reference on the response of mechanical systems to transient loads is Lord Rayleigh,¹ which treats many classical mechanical systems such as vibrating strings, rods, plates, membranes, shells, and spheres. A more recent comprehensive text on the topic is Graff,² which includes the treatment of shock waves in continua. Meirovitch³ provides an advanced treatment of mechanical response for the mathematically inclined, while Burton⁴ is a very readable text that covers the response of mechanical systems to shock. Harris and Piersol⁵ are comprehensive and include Newmark and Hall's pioneering treatment of the response of structures to ground shock. Den Hartog⁶ contains problems of practical interest, such as the rolling of ships due to wave action. The history of the U.S. Department of Defense and U.S. Department of Energy activities in shock and vibration is contained in Pusey.⁷

References on the shock loading caused by different phenomena are readily available via government and academic sources. Analytic models for air blast and ground shock loading caused by explosions can be found in the U.S. Army Corps of Engineers publication.⁸ The classic reference for explosively generated watershock is Cole.⁹ Goldsmith¹⁰ and Rinehart¹¹ cover impact phenomena, and a useful closed-form treatment of impact response is contained in Timoshenko and Goodier.¹²

References on vibration isolation can be found in Mindlin's classical work on packaging,¹³ Sevin and Pilkey,¹⁴ and Balandin, Bolotnik, and Pilkey.¹⁵

Treatments of shock response similar to this chapter can be found in Thomson and Dahleh,¹⁶ Fertis,¹⁷ Welch and White,¹⁸ and Ebeling.¹⁹

Figure 1 Single-degree-of-freedom (SDOF) system exposed to a transient force $F(t)$ and base motion $y(t)$.

3 SINGLE-DEGREE-OF-FREEDOM SYSTEMS: FORCED AND BASE-EXCITED RESPONSE

Consider the mass-spring-dashpot systems shown in Fig. 1 in which a transient force $F(t)$ is applied to the mass M . Such a system is called a single-degree-of-freedom system because it requires a single coordinate to specify the location of the mass. Let the equilibrium position of the mass (the position of the mass absent all forces) relative to an inertial reference frame be given by $x(t)$; let the location of the base to which the spring and dashpot are attached be given by $y(t)$; and let the force due the spring and the dashpot be given by F_k and F_c , respectively. Vector notation is not being used for the various quantities for simplicity and because we are dealing in only one dimension. For a linear elastic spring, with spring constant K , and a dashpot with viscous dampening constant C , the spring and dashpot forces are given by

$$-F_k = K(y - x) \quad -F_c = C(\dot{y} - \dot{x}) \quad (1)$$

where a dot over a variable indicates differentiation with respect to time. Employing Newton's second law produces

$$M\ddot{x} = F(t) - F_c - F_k$$

or

$$M\ddot{x} + C(\dot{x} - \dot{y}) + K(x - y) = F(t) \quad (2)$$

Let

$$u = x - y \quad \dot{u} = \dot{x} - \dot{y} \quad \ddot{u} = \ddot{x} - \ddot{y} \quad (3)$$

Employing Eqs. 3 in 2 produces

$$\ddot{u} + \frac{C}{M}\dot{u} + \frac{K}{M}u = \frac{F(t)}{M} - \ddot{y}(t) \quad (4)$$

Equation (4) states that for the SDOF system's response, a negative acceleration of the base, $-\ddot{y}$, is equivalent to a force $F(t)/M$ applied to the mass. This is an important result.

For reasons that will become obvious shortly, define

$$\omega_n^2 = \frac{K}{M} \quad \rho = \frac{C}{2\sqrt{KM}} \quad (5)$$

where ω_n is the natural frequency in radians/second and ρ is the damping ratio. Using Eqs. (5) in (4) produces

$$\ddot{u} + 2\rho\omega_n\dot{u} + \omega_n^2u = \frac{F(t)}{M} - \ddot{y}(t) \quad (6)$$

The complete solution to Eq. 6 (see Spiegel²⁰) consists of the solution of the homogeneous form of Eq. (6), added to the particular solution:

$$\ddot{u} + 2\rho\omega_n\dot{u} + \omega_n^2u = 0 \quad (\text{homogeneous equation}) \quad (7)$$

$$\ddot{u} + 2\rho\omega_n\dot{u} + \omega_n^2u = \frac{F(t)}{M} - \ddot{y}(t) \quad (\text{particular equation}) \quad (8)$$

Single-degree-of-freedom systems exhibit four types of behavior dependent on the value of ρ (see Thomson and Dahleh¹⁶). To illustrate these, assume there is no applied force [$F(t) = 0$] and no base acceleration ($\ddot{y} = 0$), but that the SDOF system has initial conditions of displacement and velocity given by

$$u(0) = u_1 \quad \dot{u}(0) = \dot{u}_1 \quad (9)$$

Under these conditions, the particular solution is zero, and the system's response is given by solutions to the homogeneous equation [Eq. (7)]. Such a response is termed "free vibration response" (see Chapter 12). The four types of SDOF systems, and their corresponding free vibration response, are given by^{16,20}:

For $\rho = 0$ (undamped oscillatory system):

$$u(t) = u_1 \cos \omega_n t + \frac{\dot{u}_1}{\omega_n} \sin \omega_n t \quad (10)$$

For $0 < \rho < 1$ (underdamped oscillatory system):

$$u(t) = e^{-\rho\omega_n t} \left(u_1 \cos \omega_D t + \frac{\dot{u}_1 + \rho\omega_n u_1}{\omega_D} \sin \omega_D t \right) \quad (11)$$

For $\rho = 1$ (critically damped system):

$$u(t) = e^{-\omega_n t} [u_1 + (\dot{u}_1 + \omega_n u_1)t] \quad (12)$$

For $\rho > 1$ (overdamped systems):

$$u(t) = e^{-\rho\omega_n t} \left\{ \frac{1}{2} \left[u_1 \left(1 + \rho \frac{\omega_n}{\omega_D} \right) + \frac{\dot{u}_1}{\omega_D} \right] e^{\omega_D t} + \frac{1}{2} \left[u_1 \left(1 - \rho \frac{\omega_n}{\omega_D} \right) - \frac{\dot{u}_1}{\omega_D} \right] e^{-\omega_D t} \right\} \quad (13)$$

where $\omega_D = \omega_n \sqrt{1 - \rho^2}$ (damped natural frequency). ω_n (14)

In Fig. 2, the displacement responses of the four systems for $u(0) = u_1$, $\dot{u}(0) = 0$ are shown plotted in scaled or normalized fashion as $u(t)/u_1$. Time is scaled

Figure 2 Response of undamped, underdamped, critically damped, and overdamped SDOF systems to an initial displacement u_1 .

by t/T where T is the natural period of the oscillatory systems and is given by

$$T = 1/f_n \quad (15)$$

where f_n is the natural frequency in cycles/second (or hertz) of the oscillatory SDOF systems and is given by

$$f_n = \omega_n/2\pi \quad (16)$$

It is clear from Fig. 2 that the first two systems exhibit oscillatory behavior, and the second two systems do not. The underdamped homogeneous solution converges to the undamped solution for $\rho = 0$ [Eqs. (11), (12), and (15)]. The SDOF systems encountered most often are either undamped ($\rho = 0$) or underdamped ($\rho(1)$), and from this point forward only these systems will be considered.

In Fig. 2 the natural period of the two oscillatory systems becomes apparent. Shock loading occurs when the duration, rise time, or other significant time variations of $F(t)$ or $\ddot{y}(t)$ are small as compared to the natural period of the system. These features manifest themselves as frequency components in the forcing functions or the base accelerations that are higher than the natural or characteristic frequency of the SDOF system (see next section). When pure shock loading occurs, the system responds impulsively by which the time integrals of the force or acceleration history determine the system response.

Shock loading is a matter of degree. Transient forces or accelerations whose rise time to peak are, say, one third of the system's characteristic frequency are less impulsive than forcing phenomena that are 1/100 of the system's response, but impulsive behavior begins when the forcing function $F(t)$, or base acceleration $\ddot{y}(t)$, has significant time-dependent

features shorter than the system's characteristic or natural period.

4 DUHAMEL'S INTEGRAL AND SDOF SYSTEM RESPONSE TO ZERO RISE TIME, EXPONENTIALLY DECAYING BASE ACCELERATION

The response of an underdamped or undamped SDOF system to an abrupt arbitrary force, $F(t)$, or to an abrupt arbitrary base acceleration, $\ddot{y}(t)$, can be treated quite generally using Duhamel's integral.^{5,16,17} This technique is also applicable to nonshock situations.

Impulse $I(t)$ is defined as the time integral of force,

$$I(t) = \int_0^t F(t) dt$$

From Newton's second law,

$$F(t) = M \frac{dv}{dt} \text{ or } dv = \frac{F(t) dt}{M}$$

where v is the velocity of the mass, M . This indicates that the differential change in velocity of the mass is equal to the differential impulse divided by the mass.

Now consider the arbitrary force history as shown at top of Fig. 3 that acts on the mass of an SDOF system. At some time, τ , into the force history we can identify a segment $\delta\tau$ wide with amplitude $F(\tau)$. This segment will cause a change in velocity of the SDOF mass, but in the limit as $\delta\tau$ tends toward zero, there will be no time for the system to undergo any displacement. If this segment is considered by itself, then this is

Figure 3 Arbitrary force history, $F(t)$, and an SDOF system's response to a segment $d\tau$ wide.

equivalent to initial conditions on the SDOF system at $t = \tau$ of:

$$u(\tau) = 0 \quad \dot{u}_1(\tau) = \frac{F(\tau) d\tau}{M} \quad (17)$$

From Eq. (12) we would expect the response of an underdamped SDOF system to be

$$u(t) = e^{-\rho\omega_n(t-\tau)} \left[\frac{F(\tau) d\tau}{M\omega_D} \sin \omega_D(t-\tau) \right]$$

The system's response to this segment alone of the force history is shown notionally in the bottom of Fig. 3. The SDOF systems considered thus far are linear systems. An important property of linear systems is that their response to multiple forces can be determined by adding their responses to each of the forces. Hence, to determine the response of the SDOF to the complete force history we can integrate over time, thus

$$u(t) = \frac{1}{M\omega_D} \int_0^t F(\tau) e^{-\rho\omega_n(t-\tau)} \sin \omega_D(t-\tau) d\tau \quad (18)$$

Equation (18) is known variously as Duhamel's integral, the convolution integral, or the superposition integral for an underdamped SDOF system subjected to a force $F(t)$. For $\rho = 0$, hence $\omega_D = \omega_n$, Eq. (18) reduces to the response of an undamped system to an arbitrary force. Because of the superposition property of linear systems, the response of an SDOF system to other forces or initial conditions can be found by adding these other responses to the response given by Eq. (18).

The general form of Duhamel's integral is

$$u(t) = \int_0^t F(\tau) H(t-\tau) d\tau$$

where $H(t-\tau)$ is the system's response to a unit impulse.

Referring to Eq. (8), we see that a force $F(t)/M$ is equivalent to acceleration $-\ddot{y}(t)$. Thus from Eq. (18) the Duhamel integral can be written immediately for an arbitrary base acceleration history as

$$u(t) = \frac{-1}{\omega_D} \int_0^t \ddot{y}(\tau) e^{-\rho\omega_n(t-\tau)} \sin \omega_D(t-\tau) d\tau \quad (19)$$

Equations (18) and (19) treat the general loading of underdamped and undamped SDOF systems, including that caused by shock loading. Consider now the response of an SDOF system to a shocking base acceleration, specifically an abrupt (zero rise time), exponentially decaying base acceleration of the form:

$$\ddot{y}(t) = A_m e^{-t/\beta T} \quad (20)$$

in which the acceleration begins abruptly at $t = 0$, with magnitude A_m , time decay constant β , and T is the undamped period of the SDOF system. Thus,

$$\beta T = \beta \frac{1}{f_n} = \frac{2\pi\beta}{\omega_n} \quad (21)$$

In Fig. 4 $\ddot{y}(t)$ is shown plotted as a function of normalized time (t/T) for several values of the decay constant β . Using Eq. (20) in Eq. (19) produces

$$u(t) = -\frac{A_m}{\omega_D} \int_0^t e^{-\tau/\beta T} e^{-\rho\omega_n(t-\tau)} \sin \omega_D(t-\tau) d\tau \quad (22)$$

Figure 4 Response of SDOF system to exponential base acceleration of various decay constants ($A_m = 10 \text{ m/s}^2$, $\omega_n = 10 \text{ rad/s}$, $\rho = 0.2$).

Letting

$$\omega_e = \omega_n \left(\frac{1}{2\pi\beta} - \rho \right)$$

Eq. (22) can be expressed as

$$u(t) = -\frac{A_m}{\omega_D} e^{-\rho\omega_n t} \int_0^t e^{-\omega_e \tau} \sin \omega_D(t - \tau) d\tau$$

Carrying out the integration and placing in the limits of integration produces

$$u(t) = \frac{A_m}{\omega_e^2 + \omega_D^2} e^{-\rho\omega_n t} \times \left(\cos \omega_D t - \frac{\omega_e}{\omega_D} \sin \omega_D t - e^{-\omega_e t} \right) \quad (23)$$

Double integrating Eq. (20) with respect to time produces

$$y(t) = A_m [(\beta T)t + (\beta T)^2 (e^{-t/\beta T} - 1)] \quad (24)$$

and from Eq. (3), the motion of the mass is given by $x(t) = u(t) + y(t)$. The relative displacement $u(t)$ from Eq. (24) of the SDOF system is shown plotted versus (t/T) at the bottom of Fig. 4 for several values of the decay constant β . The SDOF system in Fig. 4 has a natural frequency ω_n of 10 rad/s, damping $\rho = 0.2$, and has a peak base acceleration A_m of 10 m/s².

5 LAPLACE TRANSFORMS AND SDOF SYSTEM RESPONSE TO A VELOCITY STEP FUNCTION

One approach for estimating the response of an SDOF system to an abrupt (shock) base motion is to assume that the base motion follows that of a zero-rise-time permanent change in velocity, that is, a velocity step function (top of Fig. 5). This type of motion contains very high frequency components because of the zero-rise-time nature of the pulse (hence infinite acceleration), and significant low-frequency characteristics because of the infinite duration of the pulse. For many cases in which the base acceleration is not well quantified but is known to be quite large, while the maximum change in velocity of the base is known with some certainty, assuming this type of input provides a useful upper bound on the acceleration experienced by the SDOF mass. It is also useful in the testing of small SDOF systems because for these systems, simulating this type of input is relatively easy in the laboratory.

There are some situations in which the base motion contains frequencies of significant amplitude close to or equal to the natural frequency of the SDOF system. In these cases, the velocity step function input may not be an upper-bound estimate of the acceleration.

Figure 5 SDOF system response to a base motion consisting of a velocity step ($f_n = 100$ Hz, $\rho = 0.15$).

For a velocity step function, the base velocity is

$$\dot{y}(t) = V_0 \underline{H}(t - \xi) \quad \xi = 0 \quad (25)$$

where V_0 is the amplitude of the velocity change ($V_0 = 10$ m/s in Fig. 5), and $\underline{H}(t - \xi)$ is the modified Heaviside unit step function defined as

$$\begin{aligned} \underline{H}(t - \xi) &= 0 & \text{for } t \leq \xi \\ &= 1 & \text{for } t > \xi \end{aligned}$$

While the velocity of the base is V_0 for $t > 0$, the base velocity and displacement at $t = 0$ are given by

$$y(0) = 0 \quad \dot{y}(0) = 0 \quad (26)$$

As mentioned previously, the velocity step function exposes the SDOF system to infinite accelerations at $t = 0$ regardless of the magnitude of the velocity.

This is because this change in velocity occurs in zero time. Differentiating Eq. (25) to obtain the acceleration gives

$$\ddot{y}(t) = \frac{d[V_0 H(t - \xi)]}{dt} = V_0 \delta(t - \xi) \quad \xi = 0 \quad (27)$$

where $\delta(t - \xi)$ is the Dirac delta function whose properties are

$$\begin{aligned} \delta(t - \xi) &= \begin{cases} 0 & \text{for } t \neq \xi \\ \infty & \text{for } t = \xi \end{cases} \\ \int_{-\infty}^{\infty} \delta(t - \xi) dt &= 1 \\ \int_{-\infty}^{\infty} \delta(t - \xi) F(t) dt &= F(\xi) \end{aligned}$$

Equation (27) states that the base of the SDOF system experiences an acceleration that is infinite at $t = 0$ and zero at all other times, and that the integral of the acceleration is exactly the velocity step function of Eq. (25).

We will assume that the SDOF system mass is stationary at $t = 0$, with initial conditions:

$$x(0) = 0 \quad \dot{x}(0) = 0 \quad (28)$$

Using Eqs. (26) and (27) in Eq. (3) results in the initial condition of $u(t)$:

$$u(0) = 0 \quad \dot{u}(0) = 0 \quad (29)$$

Laplace transforms can be used to solve the differential equation of motion for this shock problem. Laplace transforms are one of several types of integral transforms (e.g., Fourier transforms) that transform differential equations into a corresponding set of algebraic equations.²⁰⁻²² The algebraic equations are then solved, and the solution is had by inverse transforming the algebraic solution. For Laplace transforms the initial conditions are incorporated into the algebraic equations.

If $g(t)$ is defined for all positive values of t , then its Laplace transform, $L[g(t)]$, is defined as

$$L[g(t)] = \int_0^{\infty} e^{-st} g(t) dt = \bar{g}(s)$$

where s is called the Laplace transform variable, and \bar{g} is used to indicate the Laplace transform of g . Similarly, letting $L[u(t)] = \bar{u}(s)$ designate the Laplace transform of u , the Laplace transform of Eq. (8), with $F(t) = 0$, becomes

$$L[\ddot{u}(t)] + L[2\rho\omega_n \dot{u}(t)] + L[\omega_n^2 u(t)] = L[-\ddot{y}(t)]$$

or

$$L[\ddot{u}(t)] + 2\rho\omega_n L[\dot{u}(t)] + \omega_n^2 L[u(t)] = -L[V_0 \delta(t)]$$

Employing the definition of the Laplace transform in the above produces

$$\begin{aligned} [s^2 \bar{u} - su(0) - \dot{u}(0)] + 2\rho\omega_n [s\bar{u} - u(0)] \\ + \omega_n^2 \bar{u} = -V_0 \end{aligned}$$

in which the initial conditions for u show up explicitly. Using Eq. (29) in the above produces

$$\bar{u} = \frac{-V_0}{s^2 + 2\rho\omega_n s + \omega_n^2} \quad (30)$$

Equation (30) can be rewritten as

$$\begin{aligned} \bar{u} &= \frac{-V_0}{(s + \rho\omega_n)^2 + \omega_n^2 - \rho^2 \omega_n^2} \\ &= \frac{-V_0}{(s + \rho\omega_n)^2 + \omega_D^2} \end{aligned} \quad (31)$$

where we have used $\omega_D = \omega_n(1 - \rho^2)^{1/2}$. The inverse transform of Eq. (31) (see Churchill²²) is

$$u(t) = \frac{-V_0}{\omega_D} e^{-\rho\omega_n t} \sin(\omega_D t) \quad (32)$$

which provides the displacement of the SDOF mass relative to the base on which it is mounted. After $t = 0$, $\dot{y}(t)$ is a constant, and the acceleration of the mass is given by

$$\ddot{x}(t) = \ddot{u}(t) + \ddot{y}(t) = \ddot{u}(t) \quad \text{for } t > 0$$

and the acceleration of the SDOF mass can be had by differentiating Eq. (32) twice with respect to time to get

$$\begin{aligned} \ddot{x}(t) &= V_0 e^{-\rho\omega_n t} [2\rho\omega_n \cos(\omega_D t) \\ &\quad + (1 - 2\rho^2)\omega_n^2/\omega_D \sin(\omega_D t)] \end{aligned} \quad (33)$$

Using the fact that

$$A \sin(\omega t + \phi) = B \sin(\omega t) + C \cos(\omega t)$$

where

$$\begin{aligned} A &= (C^2 + B^2) \\ \phi &= \arctan(C/B) \end{aligned}$$

Equation (33) becomes

$$\begin{aligned} \ddot{x}(t) &= \frac{V_0 \omega_n}{(1 - \rho^2)^{1/2}} e^{-\rho\omega_n t} \sin(\omega_D t + \phi) \\ \phi &= \arctan \left[\frac{2\rho(1 - \rho^2)^{1/2}}{(1 - 2\rho^2)} \right] \end{aligned} \quad (34)$$

At the bottom of Fig. 5, $\ddot{x}(t)$ (in units of acceleration due to gravity, $g = 9.8 \text{ m/s}^2$) from Eq. (34) is shown plotted as a function of normalized time, t/T , for an SDOF system that has characteristics $\omega = 2\pi 100 (f_n = 100 \text{ Hz})$, $\rho = 0.15$, and input base velocity $V_0 = 10 \text{ m/s}$.

We will now derive several approximate expressions for the peak acceleration experienced by an SDOF system undergoing a velocity step shock to its base (see Welch and White¹⁸). These approximations apply to SDOF systems whose dampening ratio is $\rho < 0.4$. Differentiating Eq. (34) with respect to time and setting the result equal to zero produces

$$\ddot{x}(t) = 0 = \frac{V_0 \omega_n}{(1 - \rho^2)^{1/2}} e^{-\rho \omega_n t} \times [-\rho \omega_n \sin(\omega_D t + \phi) + \omega_D \cos(\omega_D t + \phi)]$$

Solving for $t = t_p$, the time to peak acceleration, in the above and using Eqs. (15) and (34) produces

$$t_p = \frac{1}{\omega_D} \left\{ \arctan \left[\frac{(1 - \rho^2)^{1/2}}{\rho} \right] - \arctan \left[\frac{2\rho(1 - \rho^2)^{1/2}}{(1 - 2\rho^2)} \right] \right\} \quad (35)$$

For $\rho < 0.4$:

$$\begin{aligned} \arctan \left[\frac{(1 - \rho^2)^{1/2}}{\rho} \right] &\approx \frac{\pi}{2} - \rho \\ \arctan \left[\frac{2\rho(1 - \rho^2)^{1/2}}{(1 - 2\rho^2)} \right] &\approx 2\rho \end{aligned} \quad (36)$$

or

$$t_p \approx \frac{1}{\omega_D} \left(\frac{\pi}{2} - 3\rho \right) = \frac{1}{(1 - \rho^2)^{1/2} 2\pi f_n} \left(\frac{\pi}{2} - 3\rho \right) \quad (37)$$

which can be further simplified:

$$t_p \approx \frac{1}{4f_n} - \frac{3\rho}{2\pi f_n} \quad (38)$$

Equation (38) provides reasonable estimates of the time to peak acceleration for SDOF systems that have $\rho < 0.4$. It indicates that the time to peak acceleration decreases with increasing dampening and will occur at $t_p = 0$ for

$$\frac{1}{4f_n} = \frac{3\rho}{2\pi f_n}$$

or,

$$\rho = \frac{2\pi}{12} \approx 0.52$$

The actual value of ρ for $t_p = 0$ can be found from Eq. (35):

$$\arctan \left[\frac{(1 - \rho^2)^{1/2}}{\rho} \right] = \arctan \left[\frac{2\rho(1 - \rho^2)^{1/2}}{1 - 2\rho^2} \right]$$

or

$$\rho = 0.50$$

We will now develop a simplified approximate equation for the peak acceleration. For $\rho < 0.4$, using the second of Eqs. (34) and (36) we have

$$\phi = \arctan \left[\frac{2\rho(1 - \rho^2)^{1/2}}{1 - 2\rho^2} \right] \approx 2\rho \quad (39)$$

Using Eqs. (38) and (39) in the first of Eq. (34) produces for the peak acceleration \ddot{x}_p :

$$\begin{aligned} \ddot{x}_p &\approx \frac{V_0 \omega_n}{(1 - \rho^2)^{1/2}} \exp \frac{-\rho \omega_n}{\omega_D} \left(\frac{\pi}{2} - 3\rho \right) \\ &\quad \sin \left(\frac{\pi}{2} - 3\rho + 2\rho \right) \\ &= V_0 f_n \left[\frac{2\pi}{(1 - \rho^2)^{1/2}} \exp \left[\frac{-\rho}{(1 - \rho^2)^{1/2}} \right] \right. \\ &\quad \left. \left(\frac{\pi}{2} - 3\rho \right) \cos(\rho) \right] \end{aligned} \quad (40)$$

Equation (40) can be further simplified by realizing that the term within the large brackets is fairly constant over the range $0 < \rho < 0.4$, and, to 25% accuracy, Eq. (40) can be approximated by

$$\ddot{x}_p \approx 5.5 V_0 f_n \quad (41)$$

Equation (41) states that the peak acceleration experienced by an SDOF system with $\rho < 0.4$ as a result of a velocity step to its base is directly proportional to the change in the base velocity and the SDOF's natural frequency. Equation (41) can be used for rough analysis of SDOF systems subjected to shocks generated by drop tables (see Section 7) and for estimating the maximum acceleration an SDOF system experiences as a result of a shock.

6 SHOCK SPECTRA

This section describes the construction of shock spectra, which are graphs of the maximum values of acceleration, velocity, and/or displacement response of an infinite series of linear SDOF systems with constant damping ratio ρ shaken by the same acceleration history $\ddot{y}(t)$ applied at its base (Fig. 1). Each SDOF system is distinguished by the value selected for its undamped natural cyclic frequency of vibration f_n (units of cycles/second, or hertz), or equivalently, its undamped natural period of vibration T (units of seconds).

Table 1 Definition of Earthquake Response Spectrum Terms

Symbols	Definition	Description
$S_D = SD$	$ u(t) _{\max}$	Relative displacement response spectrum or spectral displacement
SV	$ \dot{u}(t) _{\max}$	Relative velocity response spectrum
SA	$ \ddot{x}(t) _{\max} = \ddot{u}(t) + \ddot{y}(t) _{\max}$	Absolute acceleration response spectrum
$S_V = PSV$	$= \omega_n S_D = 2 \pi f_n S_D$	Spectral pseudovelocity
$S_A = PSA$	$= \omega_n S_V = (\omega_n)^2 S_D = 4 \pi^2 f_n S_D$	Spectral pseudoacceleration

Note: $\omega_n = \sqrt{\frac{K}{M}}$; $\omega_n = 2 \pi f_n$; $\omega_n = \frac{2 \pi}{T}$; and $f_n = \frac{1}{T}$

In the civil engineering field of structural dynamics, an acceleration history is assigned to $\ddot{y}(t)$ in Fig. 1. This $\ddot{y}(t)$ is either an earthquake history recorded during an earthquake event or a synthetic accelerogram. The shock spectra generated using this $\ddot{y}(t)$ is referred to as response spectra (Ebeling¹⁹). Response spectra are useful not only in characterizing a design earthquake event but are directly used in the seismic design of a building by allowing for the computation of maximum displacements and internal forces.

The construction of the response spectrum plots a succession of peak response values for SDOF systems with constant damping ratio ρ and natural frequencies f_n ranging from near zero to values of tens of thousands of hertz. For each SDOF system of value f_n the dynamic response is computed using a numerical procedure like the central difference method. The dynamic response of the Fig. 1 SDOF system is expressed in terms of either the relative response or the total response of the SDOF system. Response spectrum values are the maximum response values for each of five types of SDOF responses for a system of frequency f_n and damping ρ . These five response parameters are listed in Table 1.

The value assigned to each of the five Table 1 dynamic response terms for an SDOF system is the peak response value computed during the shock. The relative displacement response spectrum, S_D , or SD, is the maximum absolute relative displacement value $|u(t)|_{\max}$ computed using numerical methods for each of the SDOF systems analyzed. The relative velocity response spectrum, SV, is the maximum absolute value of the computed relative velocity time history $|\dot{u}(t)|_{\max}$ and computed using numerical methods. The absolute acceleration response spectrum, SA, is the maximum absolute value of the sum of the computed relative acceleration time history $\ddot{u}(t)$ for the SDOF system (also computed using numerical methods) plus the ground (i.e., Fig. 1 base) acceleration history $\ddot{y}(t)$. The spectral pseudovelocity, S_V , or PSV, of the acceleration time history is computed using S_D for each SDOF system analyzed. The spectral pseudoacceleration, S_A , or PSA, of the acceleration time history $\ddot{y}(t)$ is computed using the value for S_D for each SDOF system analyzed.

The term S_V is related to the maximum strain energy stored within the linear spring portion of the SDOF system when the damping force is neglected. The

pseudovelocity values of S_V for a SDOF system of frequency f_n are not equivalent to the relative velocity value SV, as shown in Ebeling.¹⁹ This is especially true at low frequency (see Fig. 6.12.1 in Chopra²³). The prefix *pseudo* is used because S_V is not equal to the peak of the relative velocity $\dot{u}(t)$.

The S_A is distinguished from the absolute acceleration response spectrum SA. The pseudoacceleration values S_A for an SDOF system of frequency f_n are equal to the absolute acceleration value SA only when $\rho = 0$ (Ebeling¹⁹). For high-frequency, stiff SDOF systems values for S_A and SA approach the value for the peak acceleration $|\ddot{y}(t)|_{\max}$. As the frequency f_n approaches zero, the values for S_A and SA approach zero.

The following paragraph discusses an example construction of a response spectrum for an infinite series of linear SDOF systems shaken by the Fig. 6 acceleration history. Figure 6 is the top of powerhouse substructure (total) acceleration history response to a synthetic accelerogram representing a design earthquake in the Ebeling et al.²⁴ seismic evaluation of Corps of Engineers' powerhouse substructures. Peak ground (i.e., at base) acceleration is 0.415g.

In practical applications, each of the five response spectrum values is often plotted as the ordinate versus values of system frequencies f_n along the abscissa for a series of SDOF systems of constant damping ρ . Alternatively, a compact four-way plot that replaces three of these plots (of S_D , S_V , and S_A) with a single plot is the tripartite response spectra. Figure 7 shows the tripartite response spectra plot for the Fig. 6 acceleration history $\ddot{y}(t)$ for 2 and 5% damping. A log-log scale is used with S_V plotted along the ordinate

Figure 6 Acceleration time history computed at the top of an idealized powerhouse substructure. (From Ebeling et al.²⁴)

Figure 7 Response spectra for a top of powerhouse substructure amplification study acceleration time history; $\rho = 2\%$ and 5% . (From Ebeling et al.²⁴)

and f_n along the abscissa. Two additional logarithmic scales are shown in Fig. 7 for values of S_D and S_A and sloping at -45° and $+45^\circ$, respectively, to the f_n axis. Another advantage of the tripartite response spectra plot is the ability to identify three spectral regions in which ranges in natural frequencies of SDOF systems are sensitive to acceleration, velocity, and displacement, respectively, as identified in Fig. 7.

We observe that for civil engineering structures with high frequency, say f_n greater than 30 Hz, S_A for all damping values approaches the peak ground acceleration of $0.415g$ and S_D is very small. For a fixed mass, a high-frequency SDOF system is extremely stiff or essentially rigid; its mass would move rigidly with the ground (i.e., the base). Conversely, for the left side of the plot for low-frequency systems and for a fixed mass, the system is extremely flexible; the mass would be expected to remain essentially stationary while the ground below moves and its absolute and relative accelerations will approach zero.

7 SHOCK TESTING METHODS AND DEVICES

The theoretical developments described thus far assume that the physical characteristics of the mechanical systems and the forcing functions or base motions are known. These kinds of data are gathered through experimental methods. There are four primary types of testing devices for determining the characteristics of mechanical systems: load deflection devices, harmonically oscillating shaker machines, impact testing machines, and programmable hydraulic-actuator machines.

Load deflection devices are used to determine the spring–force deflection curves for mechanical systems. For a linear spring, the slope of the force–deflection curve is equal to the spring constant K . Load deflection devices can be of a variety of types. Weights can be used to load the mechanical systems, in which case the load is equivalent to the weight used, or hydraulic or screw-type presses can be used to load the mechanical system in which case the load is measured using commercial load cells. Commercial load cells usually consist of simple steel structures in which one member is strain gaged using foil or semiconductor strain gages (see Perry and Lissner²⁵). The deformation of the strain-gaged member is calibrated in terms of the load applied to the load cell. A simple load cell is a moderately long (length-to-diameter ratio of 4 or more), circular cross-section column loaded parallel to its axis. Axial and Poisson strains recorded near its midpoint are directly related to the load applied through the Young's modulus and Poisson's ratio of the load cell material. The resultant deflection of the mechanical system is monitored using commercially available deflection sensors such as linear-variable displacement sensors, magnetic displacement sensors, or optical sensors. While load deflection devices provide data on the spring forces of a mechanical system, they provide no information on its dampening characteristics.

Harmonic motion shaker machines range in size from a few pounds to several tons (Fig. 8). The shaker machines are of two types: piezoelectric driven and electromagnetic driven. Their purpose is to derive the frequency response characteristics of the mechanical system under test normally by driving the base of the mechanical system with a harmonic motion that is swept in frequency (see Frequency Response Functions, Chapter 12). The piezoelectric crystal machines use the piezoelectric effect to drive the mechanical system. The piezoelectric effect is manifested in some crystalline structures in which a voltage applied to opposite surfaces of the crystal causes the crystal to

Figure 8 Early Los Alamos National Laboratory electrodynamic shaker capable of generating peak forces of 22,000 lb. (From Pusey.⁷)

Figure 9 Los Alamos National Laboratory 150-ft drop tower. (From Pusey.⁷)

change its dimensions. Alternatively, if the crystal is compressed or elongated, a voltage will be produced on these surfaces; thus this piezoelectric effect can also be used as a sensing method. Electromagnetic shakers use a magnet-in-wire coil structure similar to an electromagnetic acoustical speaker. A voltage applied to the coil causes the magnet to displace. Piezoelectric shakers are capable of higher frequencies but

Photograph of Drop Table

Figure 10 Photo and cross section of commercial drop table.

have lower peak displacements than electromagnetic shakers. While shakers are usually used to produce harmonic motion of the base of the mechanical system, they can also be used to generate random vibratory or short impulsive input. The frequency response and damping characteristics in all cases are determined by comparing the input base motion at particular frequencies to the resultant motion of the mechanical system at the same frequency. The input and response motions are often monitored via commercially available accelerometers. For the random or impulse case, the frequency content and phase of the input and

Figure 11 U.S. Navy medium-weight shock machine. (From Pusey.⁷)

mechanical system response are derived by performing fast Fourier transforms (Hamming²⁶) on the associated signals. The frequency and phase data are then used to derive the frequency response functions (Chapter 13).

Impact testing lends itself to a multitude of test methods. The simplest form of impact testing is the drop test in which the mechanical system under study is dropped from a known distance onto a rigid surface. The mechanical system's response is monitored through impact to derive its response characteristics. Mindlin¹³ provides additional information and is a classic reference on drop testing. An extreme case of drop testing device built by the Lawrence Livermore National Laboratory is the 150-ft drop tower shown in Fig. 9 (page 221). To provide more precise control of the drop test, commercially available drop tables are used, an example of which is shown in Fig. 10. In the drop table test machine, a falling test platform is constrained in its ballistic fall by two or more guide bars. The item under test is rigidly attached to the test platform. The test platform is coupled to the guide bars through sleeve or roller bearings to ensure consistent and smooth operation. The falling platform impacts a controlled surface either directly or through

Figure 12 Los Alamos National Laboratory 24-inch bore gas gun. (From Pusey.⁷)

an impacting material such as an engineered crushable foam or expanded metal structure. The control surface may be rigid or may itself be mounted through a spring-mass-dashpot system to a rigid surface. By using a drop table, the orientation of the test sample, the contact surfaces, and the velocity at impact are controlled.

Several types of impact test machines were developed by the U.S. Navy (Pusey⁷). These include the light-weight and medium-weight shock machines (Fig. 11). The two types of machines are of similar design, with the light-weight machine being used to shock test lighter equipment than the medium-weight machine. For both machines the test specimen is mounted on an anvil table of prescribed mass and shape. For the medium-weight shock machine a large (3000-lb) hammer is dropped through a circular arc section and impacts from below a 4500-lb anvil table containing the test item.

Another type of impact device is the gas gun. A familiar and small form of a gas gun is a pellet or BB rifle. Gas guns use compressed air to accelerate a test article to a maximum velocity, and then the article is allowed to impact a prescribed surface. The item under test is sometimes the projectile and sometimes the target being impacted. Figure 12 shows a 24-inch bore

Figure 13 A 4-ft-diameter vertical gas gun developed at the U.S. Army Engineer Waterways Experiment Station (WES). (From White et al.²⁷)

horizontal gas gun developed from a 16-inch naval gun by the Los Alamos National Laboratory. Using 3000-psi compressed air, it was capable of accelerating a 200-lb test article to velocities of 1700 ft/s. Figure 13 shows the 4-ft-diameter vertical gas gun developed by the U.S. Army Corps of Engineers (White et al.²⁷). The device is capable of accelerating a 4-ft-diameter, 3500-lb projectile to velocities of 210 ft/s. It was used to generate shock waves in soils and to shock test small buried structures such as ground shock instruments. Sample soil stress waveforms produced by the gun in Ottawa Sand are shown in Fig. 14 (White²⁸).

Programmable hydraulic actuator machines consist of one or more hydraulic actuators with one end affixed to a test table or structure and the other end affixed to a rigid and stationary surface. The forces and motions delivered to the test table by the actuators are normally controlled via digital feedback loops. The position and orientation of the actuators allow the effects of several directions of motion to be tested simultaneously. Test specimens can be accommodated on the larger devices that range from a few pounds to several thousands of pounds. The input from the actuators is prescribed and controlled through digital computers. Programmable hydraulic actuator machines have been used to simulate the effects of earthquakes on $\frac{1}{4}$ -scale reinforced concrete multistory structures, the effects of launch vibrations on a U.S. space shuttle, the effects of nuclear-generated ground shock on underground shelter equipment, and other loading environments. Hydraulic actuators can provide for

large displacements and precisely controlled loading conditions.

CHAPTER 15

PASSIVE DAMPING

Daniel J. Inman
 Department of Mechanical Engineering
 Virginia Polytechnic Institute and State University
 Blacksburg, Virginia

1 INTRODUCTION

Damping involves the forces acting on a vibrating system so that energy is removed from the system. The phenomenon is caused through a variety of mechanisms: impacts, sliding or other friction, fluid flow around a moving mass (including sound radiation), and internal or molecular mechanisms that dissipate energy through heat (viscoelastic mechanisms). Damping, unlike stiffness and inertia, is a dynamic quantity that is not easily deduced from physical logic and cannot be measured using static experiments. Thus, it is generally more difficult to describe and understand. The concept of damping is introduced in vibration analysis to account for energy dissipation in structures and machines. In fact, viscous damping, the most common form of damping used in vibration analysis, is chosen for modeling because it allows an analytical solution of the equations of motion rather than because it models the physics correctly. The basic problems are: modeling the physical phenomena of energy dissipation in order to produce predictive analytical models, and creating treatments, designs, and add-on systems that will increase the damping in a mechanical system in order to reduce structural fatigue, noise, and vibration.

2 FREE VIBRATION DECAY

Most systems exhibit some sort of natural damping that causes the vibration in the absence of external forces to die out or decay with time. As forces proportional to acceleration are inertial and those associated with stiffness are proportional to displacement, viscous damping is a nonconservative force that is velocity dependent. The equation of motion of a single degree of freedom system with a nonconservative viscous damping force is of the form:

$$m\ddot{x}(t) + c\dot{x}(t) + kx(t) = F(t) \quad (1)$$

Here m is the mass, c is the damping coefficient, k is the stiffness, $F(t)$ is an applied force, $x(t)$ is the displacement, and the overdots denote differentiation with respect to the time t . To start the motion in the absence of an applied force, the system and hence Eq. (1) is subject to two initial conditions:

$$x(0) = x_0 \text{ and } \dot{x}(0) = v_0$$

Here the initial displacement is given by x_0 and the initial velocity by v_0 . The model used in Eq. (1)

is referred to as *linear viscous damping* and serves as a model for many different kinds of mechanisms (such as air damping, strain rate damping, various internal damping mechanisms) because it is simple, easy to solve analytically, and often gives a good approximation of measured energy dissipation.

The single-degree-of-freedom model of Eq. (1) can be written in terms of the dimensionless damping ratio by dividing (1) by the mass m to get

$$\ddot{x}(t) + 2\zeta\omega_n\dot{x}(t) + \omega_n^2x(t) = f(t) \quad (2)$$

where the natural frequency is defined as $\omega_n = \sqrt{k/m}$ (in radians per second), and the dimensionless *damping ratio* is defined by $\zeta = c/2\sqrt{km}$. The nature of the solutions to Eqs. (1) and (2) depend entirely on the magnitude of the damping ratio. If ζ is greater or equal to 1, then no oscillation occurs in the free response [$F(t) = 0$]. Such systems are called *critically damped* ($\zeta = 1$) or *overdamped* ($\zeta > 1$). The unique value of $\zeta = 1$ corresponds to the critical damping coefficient given by

$$c_{cr} = 2\sqrt{km}$$

However, the most common case occurs when $0 < \zeta < 1$, in which case the system is said to be *underdamped* and the solution is a decaying oscillation of the form:

$$x(t) = Ae^{-\omega_n\zeta t} \sin(\omega_d t + \phi) \quad (3)$$

Here A and ϕ are constants determined by the initial conditions, and $\omega_d = \omega_n\sqrt{1 - \zeta^2}$ is the damped natural frequency. It is easy to see from the solution given in Eq. (3) that the larger the damping ratio is, the faster any free response will decay.

Fitting the form of Eq. (3) to the measured free response of a vibrating system allows determination of the damping ratio ζ . Then knowledge of ζ , m , and k allow the viscous damping coefficient c to be determined.¹ The value of ζ can be determined experimentally in the underdamped case from the logarithmic decrement. Let $x(t_1)$ and $x(t_2)$ be measurements of unforced response of the system described by Eq. (1) made one period apart ($t_2 = t_1 + 2\pi/\omega_d$). Then the *logarithmic decrement* is defined by

$$\delta = \ln \frac{x(t_1)}{x(t_2)} = \ln e^{\zeta\omega_n(2\pi/\omega_d)} = \frac{2\pi\zeta}{\sqrt{1 - \zeta^2}} \quad (4)$$

Table 1 Some Common Nonlinear Damping Models^a

Coulomb damping	$\mu mg \operatorname{sgn}(\dot{x})$
Air damping	$a \operatorname{sgn}(x)\dot{x}^2$
Material damping	$d \operatorname{sgn}(\dot{x})x^2$
Structural damping	$b \operatorname{sgn}(\dot{x}) x $

^a Sgn is the signum function that takes the sign of the argument and the constants a , b , and d are coefficients of the respective damping forces.

The logarithmic decrement is determined by measurements, from the left side of Eq. (4) and provides a measurement of ζ through the right-hand side of Eq. (4). This yields

$$\zeta = \frac{\delta}{\sqrt{4\pi^2 + \delta^2}} \quad (5)$$

Unfortunately, this simple measurement of damping does not extend to more complex systems.²

The simple single-degree-of-freedom model given in Eq. (2) forms a basis for discussing damping in much more complex systems. By decoupling the equations of motion of multiple-degree-of-freedom systems and distributed mass systems (using modal analysis), the damping ratio is used to discuss damping in almost all linear systems. In addition, insight into nonlinear damping effects can be obtained by analyzing Eq. (1) numerically with the velocity term replaced with various models such as those listed in Table 1.

The presence of nonlinear damping mechanisms greatly changes the nature of the response and the behavior of the system. In general, the concept of a single static equilibrium position associated with the linear system of Eq. (1) gives way to the concept of multiple or even infinite equilibrium points. For example, with Coulomb damping, a displaced particle will oscillate with linear, rather than exponential, decay and come to rest, not at the starting equilibrium point, but rather anywhere in a region defined by the static friction force (i.e., any point in this region is an equilibrium point). In general, analytical solutions for systems with the damping mechanisms listed in Table 1 are not available and hence numerical solutions must be used to simulate the response. Joints and other connection points are often the source of nonlinear damping mechanisms.³

3 EFFECTS ON THE FORCED RESPONSE

When the system described by Eq. (1) is subjected to a harmonic driving force, $F(t) = F_0 \cos(\omega t)$, the phenomenon of resonance can occur. Resonance occurs when the displacement response of the forced system achieves its maximum amplitude. This happens if the driving frequency ω is at or near the natural frequency ω_n . In fact, without damping, the response is a sinusoid with ever-increasing amplitude, eventually causing the system to respond in its nonlinear region and/or break. The presence of damping, however,

removes the solution of ever-increasing amplitude and renders a solution of the form [for $F(t) = F_0 \cos \omega t$]:

$$x(t) = \underbrace{Ae^{-\zeta\omega_n t} \sin(\omega_d t + \phi)}_{\text{transient}} + \underbrace{X \cos(\omega t - \theta)}_{\text{steady state}} \quad (6)$$

Here A and ϕ are constants of integration determined by the initial conditions, X is the steady-state magnitude and θ is the phase shift of the steady-state response. The displacement magnitude and phase of the steady-state response are given by

$$X = \frac{F_0}{\sqrt{(\omega_n^2 - \omega^2)^2 + (2\zeta\omega_n\omega)^2}}, \quad \theta = \tan^{-1} \left(\frac{2\zeta\omega_n\omega}{\omega_n^2 - \omega^2} \right) \quad (7)$$

Equation (7) shows that the effect of damping on the response of a system to a harmonic input is to reduce the amplitude of the steady-state response and to introduce a phase shift between the driving force and the response.

Through the use of Fourier analysis and the definition of linearity, the response of a linear damped system to a general force will be some combination of terms such as those given in (6) with a transient term that dies out (quickly if ζ is large) and a steady-state term with amplitude dependent on the inverse of the damping ratio. Thus it is easy to conclude that increasing the damping in a system generally reduces the amplitude of the response of the system. With this as a premise many devices and treatments have been invented to provide increased damping as a mechanism for reducing unwanted vibration.

4 COMPLEX MODULUS

The concept of complex modulus includes an alternative representation of damping related to the notion of complex stiffness. A complex stiffness can be derived from Eq. (1) by representing a harmonic input force as a complex exponential: $F(t) = F_0 e^{j\omega t}$. Using this complex function representation of the harmonic driving force introduces a complex function response in the equation of motion, and it is the real part of this response that is interpreted as the physical response of the system. Substitution of this form into Eq. (1) and assuming the solution is of the complex form $X(t) = X e^{j\omega t}$ yields

$$\left[-m\omega^2 + \underbrace{k \left(1 + \frac{\omega c}{k} j \right)}_{k^*} \right] X = F_0 \quad (8)$$

Here k^* is called the complex stiffness and has the form

$$k^* = k(1 + \bar{\eta}j) \quad \bar{\eta} = \frac{c}{k}\omega \quad (9)$$

where $\bar{\eta}$ is called the *loss factor*, another common way to characterize damping. Note that the complex

stiffness is just an alternative way to represent the viscous damping appearing in Eq. (1). However, the concepts of loss factor and complex modulus actually carry deeper notions of temperature dependence, frequency dependence, and hysteresis as discussed in the following (see Chapter 60 for details).

Note from the form of the loss factor given in Eq. (9) that its value depends on the driving frequency. Also note that this form of describing the damping also depends on the system being driven harmonically at a single frequency. This notion of complex stiffness is sometimes referred to as Kelvin–Voigt damping and is often used to represent the internal damping of certain materials. Viscoelastic materials (rubberlike materials) are often modeled using the notion of loss factor and complex stiffness.^{4,5}

The concept of complex modulus is similar to that of complex stiffness. Let E^* denote the complex modulus of a material and E denote its elastic modulus. The complex modulus is defined by

$$E^* = E(1 + j\eta) \quad (10)$$

where η is the loss factor of the viscoelastic material. The loss factor is determined experimentally by driving a material coupon harmonically at a single frequency and fixed temperature, then measuring the energy lost per cycle. This procedure is repeated for a range of frequencies and temperatures resulting in plots of $\eta(\omega)$ for a fixed temperature (T) and $\eta(T)$ for a fixed frequency. Unfortunately, such models are not readily suitable for transient vibration analysis or for broadband excitations, impulsive loads, and the like.

Since the stiffness of an object is easily related to the modulus of the material it is made of, the notions of complex stiffness and complex modulus give rise to an equivalent value of the loss factor so that $\eta = \bar{\eta}$ (provided the elastic system consists of a single material and is uniformly strained). In the event that the system is driven at its natural frequency, the damping ratio and the loss factor are related by $\eta = 2\zeta$, providing a connection between the viscous damping model and the complex modulus and loss factor approach.^{2,4}

The complex modulus approach is also associated with the notion of hysteresis and hysteretic damping common in viscoelastic materials.⁶ Hysteresis refers to the notion that energy dissipation is modeled by a hysteresis loop obtained from plotting the stress versus strain curve for a sample material while it undergoes a complete cycle of a harmonic response. For damped systems the stress–strain curve under cyclic loading is not single valued (as it is for pure stiffness) but forms a loop. This is illustrated in Fig. 1, which is a plot of $F(t) = c\dot{x}(t) + kx(t)$ versus $x(t)$.

The area inside the hysteresis loop corresponds to the energy dissipated per cycle. Materials are often tested by measuring the stress (force) and strain (displacement) under carefully controlled steady-state harmonic loading. For linear systems with viscous

Figure 1 Plot of force $[c\dot{x}(t) + kx(t)]$ versus displacement, defining the hysteresis loop for a viscously damped system.

Figure 2 Sample experimental stress versus strain plot for one cycle of a harmonically loaded material in steady state illustrating a hysteresis loop for some sort of internal damping.

damping the shape of the hysteresis loop is an ellipse as indicated in Fig. 1. For all other damping mechanisms of Table 1, the shape of the hysteresis loop is distorted. Such tests produce hysteresis loops of the form shown in Fig. 2. Note that, for increasing strain (loading), the path is different than for decreasing strain (unloading). This type of damping is often called hysteretic damping, solid damping, or structural damping.

5 MULTIPLE-DEGREE-OF-FREEDOM SYSTEMS

Lumped mass systems with multiple degrees of freedom provide common models for use in vibration and noise studies, partially because of the tremendous success of finite element modeling (FEM) methods. Lumped mass models, whether produced directly by the use of Newton's law or by use of FEM,

result in equations of motion of the form (see also Chapter 12):

$$M\ddot{\mathbf{x}}(t) + C\dot{\mathbf{x}}(t) + K\mathbf{x}(t) = \mathbf{F}(t) \quad (11)$$

Here M is the mass matrix, K is the stiffness matrix (both of dimension $n \times n$ where n is the number of degrees of freedom), $\mathbf{x}(t)$ is the n vector of displacements, the overdots represent differentiation with respect to time, $\mathbf{F}(t)$ is an n vector of external forces, and the $n \times n$ matrix C represents the linear viscous damping in the structure or machine being modeled. Equation (11) is subject to the initial conditions:

$$\mathbf{x}(0) = \mathbf{x}_0 \quad \dot{\mathbf{x}}(0) = \dot{\mathbf{x}}_0$$

In general, the matrices M , C , and K are assumed to be real valued, symmetric, and positive definite (for exceptions see Inman⁵). As in the single-degree-of-freedom case, the choice of damping force in Eq. (11) is more one of convenience than of one based on physics. However, solutions to Eq. (11) closely resemble experimental responses of structures rendering Eq. (11) useful in many modeling situations.²

The most useful form of Eq. (11) is when the damping matrix C is such that the equations of motion can be decoupled by an eigenvalue-preserving transformation (usually called the modal matrix, as it consists of the eigenvectors of the undamped system). The mathematical condition that allows the decoupling of the equations of motion into n single-degree-of-freedom equations identical to Eq. (2) is simply that $CM^{-1}K = KM^{-1}C$, which happens if and only if the product $CM^{-1}K$ is a symmetric matrix.⁷ In this case the mode shapes of the undamped system are also modes of the damped system. This gives rise to calling such systems “normal mode systems.” In addition, if this matrix condition is not satisfied and the system modes are all underdamped, then the mode shapes will not be real but rather complex valued, and such systems are called *complex mode systems*. A subset of damping matrices that satisfies the matrix condition are those that have damping matrix made up of a linear combination of mass and stiffness, that is, $C = \alpha M + \beta K$, where α and β are constant scalars. Such systems are called *proportionally damped* and also give rise to real normal mode shapes.

Let the matrix L denote the Cholesky factor of the positive definite matrix M . A Cholesky factor¹ is a lower triangular matrix such that $M = LL^T$. Then premultiplying Eq. (11) by L^{-1} and substituting $\mathbf{x} = L^{-T}\mathbf{q}$ yields a mass normalized stiffness matrix $\tilde{K} = L^{-1}KL^{-T}$, which is both symmetric and positive definite if K is. From the theory of matrices, the eigenvalue problem for \tilde{K} , $\tilde{K}\mathbf{u}_i = \lambda_i\mathbf{u}_i$, is symmetric and thus yields real-valued eigenvectors forming a basis, and positive real eigenvalues λ_i . If the eigenvectors \mathbf{u} are normalized and used as the columns of a matrix P , then $P^T P = I$ the identity

matrix and $P^T \tilde{K} P = \text{diag}[\omega_i^2]$. Furthermore, if the damping matrix causes $CM^{-1}K$ to be symmetric, then $P^T \tilde{C} P = \text{diag}[2\zeta_i\omega_i]$, which defines the modal damping ratios ζ_i . In this case the equations of motion decouple into n single-degree-of-freedom systems, called *modal equations*, of the form:

$$\ddot{r}_i(t) + 2\zeta_i\omega_i\dot{r}_i(t) + \omega_i^2 r_i(t) = f_i(t) \quad (12)$$

These modal equations are compatible with modal measurements of ζ_i and ω_i and form the basis for modal testing.²

If, on the other hand, the matrix $CM^{-1}K$ is not symmetric, the equations of motion given in Eq. (11) will not decouple into modal equations such as (12). In this case, state-space methods must be used to analyze the vibrations of a damped system. The state-space approach transforms the second-order vector differential equation given in (11) into the first-order form:

$$\dot{\mathbf{y}} = A\mathbf{y} + B\mathbf{F}(t) \quad (13)$$

Here the state matrix A and input matrix have the form:

$$A = \begin{bmatrix} 0 & I \\ -M^{-1}K & -M^{-1}C \end{bmatrix} \quad B = \begin{bmatrix} 0 \\ M^{-1} \end{bmatrix} \quad (14)$$

The state vector \mathbf{y} has the form:

$$\mathbf{y} = \begin{bmatrix} \mathbf{x} \\ \dot{\mathbf{x}} \end{bmatrix} \quad (15)$$

This first-order form of the equations of motion can be solved by appealing to the general eigenvalue problem $A\mathbf{v} = \lambda\mathbf{v}$ to compute the natural frequencies and mode shapes. In addition Eq. (11) can be numerically simulated to produce the time response of the system. If each mode is underdamped, then from the above arguments the eigenvalues of the state matrix A will be complex valued, say $\lambda = \alpha + \beta j$. Then the natural frequencies and damping ratios are determined by

$$\omega_i = \sqrt{\alpha_i^2 + \beta_i^2} \quad \text{and} \quad \zeta_i = \frac{-\alpha_i}{\sqrt{\alpha_i^2 + \beta_i^2}} \quad (16)$$

In both the proportional damping case and the complex mode case the damping ratio can be measured using modal testing methods if the damping matrix is not known. The above formulas can be used to determine modal damping if the damping matrix is known.

In the preceding analysis, it was assumed that each mode was underdamped. This is usually the case, even with highly damped materials. If the damping matrix happens to be known numerically, then the condition

that each mode is underdamped will follow if the matrix $4\tilde{K} - \tilde{C}^2$ is positive definite.⁸

In general, finite element methods are used to produce very accurate mass and stiffness matrices. However, when it comes to determining a damping matrix for a given machine or structure, the choice is not clear, nor does the choice follow from a sophisticated procedure. Many research articles have been written about methods of determining the damping matrix, but, in practice, C is developed in an ad hoc manner, usually in an attempt to model the response with classical normal modes.

Several approaches have been developed to relate the complex modulus and frequency-dependent loss factor models to FEM.⁹ Many damping treatments are designed based on distributed mass models of basic structural elements such as bars, beams, plates, and shells. The basic equations of motion can be represented and best understood in operator notation (similar to the matrix notation used for lumped mass systems¹⁰). The modal decoupling condition is similar to the matrix case and requires that the damping and stiffness operators commute.¹¹ Examples of the form that the damping and stiffness operators take on are available in the literature.¹²

The complex eigenvalue analysis given in Eq. (16) forms a major method for use in the analysis and design of damping solutions for structures and machines. The solution is modeled, and then an eigenvalue analysis is performed to see if the modal damping has increased to an acceptable level. An alternate and more illuminating method of design is called the *modal strain energy* (MSE)^{13,14} method. In the MSE method the modal damping of a structure is approximated by

$$\eta(r) = \sum_{j=1}^M \eta_j \frac{SE_j(r)}{SE(r)} \quad (17)$$

Here $SE_j(r)$ is the strain energy in the j th material when deformed in the r th mode shape, $SE(r)$ is the strain energy in the r th mode and η_j is the material loss factor for j th material. The MSE approach is valuable for determining placement of devices and layers, for determining optimal parameters, and for understanding the general effects of proposed damping solutions.¹⁴

6 SURFACE DAMPING TREATMENTS

Many systems and structures do not have enough internal or natural damping to limit vibrations to acceptable levels. Most structures made of sheet metal, for instance, have damping ratios of the order of 0.001 and will hence ring and vibrate for unacceptable lengths of time at unacceptable magnitudes. A simple fix for such systems is to coat the surface of the structure with a damping material, usually a viscoelastic material (similar to rubber). In fact, every automobile body produced is treated with a surface

damping treatment to reduce road and engine noise transmitted into the interior.

Adding a viscoelastic layer to a metal substrate adds damping because as the host structure bends in vibration, it strains the viscoelastic material in shear causing energy to be dissipated by heat. This notion of layering viscoelastic material onto the surface of a sheet of metal is known as a *free-layer damping treatment*. By adding a third layer on top of the viscoelastic that is stiff (and often thin). The top of the boundary of the viscoelastic material tries not to move, increasing the shear and causing greater energy dissipation. Such treatments are called *constrained layer damping treatments*.

The preliminary analysis of layered damping treatments is usually performed by examining a pinned-pinned beam with a layer of viscoelastic material on top of it. A smeared modulus formula for this sandwich beam is derived to produce a composite modulus in terms of the modulus, thickness, and inertia of each layer. Then the individual modulus value of the viscoelastic layer is replaced with its complex modulus representation to produce a loss factor for the entire system. In this way thickness, percent coverage and modulus can be designed from simple algebraic formulas.⁴ This forms the topic of Chapter 60.

Other interesting surface damping treatments consist of using a piezoceramic material usually in the form of a thin patch layered onto the surface of a beam or platelike structure.¹⁵ As the surface bends, the piezoceramic strains and the piezoelectric effect causes a voltage to be produced across the piezoceramic layer. If an electrical resistor is attached across the piezoceramic layer, then energy is dissipated as heat and the system behaves exactly like a free layer viscoelastic damping treatment (called a *shunt damper*). In this case the loss factor of the treated system can be shown to be

$$\eta(\omega) = \frac{\rho k^2}{(1 - k^2) + \rho^2} \quad (18)$$

where k is the electromechanical coupling coefficient of the piezoceramic layer and $\rho = RC\omega$. The value of R is the added resistance (ohms) and C is the value of the capacitance of the piezoceramic layer in its clamped state. In general, for a fixed amount of mass, a viscoelastic layer provides more damping, but the piezoceramic treatment is much less temperature sensitive than a typical viscoelastic treatment. If an inductor is added to the resistor across the piezoceramic, the system behaves like a vibration absorber or tuned mass damper. This inductive shunt is very effective but needs large inductance values requiring synthetic inductors, which may not be practical.

7 DAMPING DEVICES

Damping devices consist of vibration absorbers, tuned mass dampers, shock absorbers, eddy current dampers, particle dampers, strut mechanisms, and various other inventions to reduce vibrations. Vibration isolators are an effective way to reduce unwanted

Table 2 Some Design Considerations for Various Add-on Damping Treatments

	Layered Damping	Tuned Mass Damper	PZT ^a Resistive Shunt	PZT ^a Inductive Shunt	Shocks Struts Links
Target modes	Bending extension	Any	Bending extension	Bending Extension	Global

vibration also. However, isolators are not energy-dissipating (damping) devices but rather are designed around stiffness considerations to reduce the transmission of steady-state magnitudes. Isolators often have damping characteristics and their damping properties may greatly affect the isolation design. Isolators are designed in the load path of a vibrating mass and in the case of harmonic disturbances are designed by choosing the spring stiffness such that either the transmitted force or displacement is reduced (See Chapter 59).

Vibration absorbers and tuned mass dampers on the other hand are add on devices and do not appear in the load path of the disturbance. Again, basic absorber design for harmonic inputs involves stiffness and mass and not damping. However, damping plays a key role in many absorber designs and is usually present whether desired or not.

Eddy current dampers consist of devices that pass a metallic structural component through a magnetic field. They are very powerful and can often obtain large damping ratios. Particle dampers work by dissipating energy through impacts of the particles against the particles' container and are also very effective. However, neither of these methods are commercially developed or well analyzed. Shock absorbers and strut dampers are energy dissipation devices that are placed in the load path (such as an automobile shock absorber). Shocks are often oil-filled devices that cause oil to flow through an orifice giving a viscous effect, often modeled as a linear viscous damping term. However, they are usually nonlinear across their entire range of travel. Table 2 indicates the analysis considerations often used for the design of various add-on damping treatments.

CHAPTER 16

STRUCTURE-BORNE ENERGY FLOW

Goran Pavić

INSA Laboratoire Vibrations Acoustique (LVA)
Villeurbanne, France

1 INTRODUCTION

Structure-borne vibration produces mechanical energy flow. The flow results from the interaction between dynamic stresses and vibratory movements of the structure. The energy flow at any single point represents the instantaneous rate of energy transfer per unit area in a given direction. This flow is called the structure-borne intensity. Following its definition, the intensity represents a vector quantity. When integrating the normal component of intensity across an area within the body, the total mechanical energy flow rate through this area is obtained.

The intensity vector changes both its magnitude and direction in time. In order to compare energy flows at various locations in a meaningful way, it is the time-averaged (net) intensity that should be analyzed. Thus, the intensity concept is best associated with stationary vibration fields.

Experimental measurements of vibration energy flow through a structure enables identification of the positions of vibratory sources, vibration propagation paths, and absorption areas. Energy flow information is primarily dedicated to source characterization, system identification, and vibration diagnostics. Information provided by energy flow cannot be assessed by simply observing vibration levels. The structure intensity or energy flow in structures can be obtained either by measurement or by computation, depending on the nature of the problem being considered. Measurements are used for diagnostic or source identification purposes, while computation can be a valuable supplementary tool for noise and vibration prediction during the design stage.

2 ENERGY FLOW CONCEPTS

From the conceptual point of view, the energy flow (EF) carried by structure-borne vibration can be looked upon in three complementary ways:

1. The basic way to look at energy flow is via the intensity concept, where the structure-borne intensity (SI), that is, the energy flow per unit area, is used in a way comparable to using stress data in an analysis of structural strength. This concept is completely analogous to acoustic intensity. An SI analysis is, however, limited to computation only, as any measurement of practical use made on an object of complex shape has to be restricted to the exterior surfaces.
2. Structures of uniform thickness (plates, shells) can be more appropriately analyzed by integrating SI across the thickness. In this way, a unit

energy flow (UEF), that is, the flow of energy per unit length in a given direction tangential to the surface, is obtained. If the energy exchange between the outer surfaces and the surrounding medium is small in comparison with the flow within the structure, as it is usually for objects in contact with air, then the UEF vector lies in the neutral layer. For thin-walled structures where the wavelengths are much larger than the thickness, UEF can be expressed in terms of outer-surface quantities, which are readily measurable. The UEF concept is best utilized for source localization.

3. Structural parts that form waveguides or simple structural joints are most easily analyzed by means of the concept of total energy flow (TEF). Some parts, such as beams and elastic mountings, possess a simple enough shape to allow straightforward expression of the EF in terms of surface vibration. The TEF in more complex mechanical waveguides, such as fluid-filled pipes, can be evaluated by more elaborate procedures, such as the wave decomposition technique.

The structure-borne intensity (SI) is a vector quantity. The three components of an SI vector read¹

$$I = -\sigma \dot{u} \quad (1)$$

where $I = [I_x, I_y, I_z]^T$ is the column of x , y , and z intensity components, σ is the 3×3 matrix of dynamic stress, \dot{u} is the column of particle velocity components (a dot indicates time derivative), and superscript T indicates transpose. The negative sign in (1) is the consequence of sign convention: The compression stresses are considered negative. Since the shear stress components obey reciprocity, $\sigma_{xy} = \sigma_{yx}$, and so on, the complete SI vector is built up of nine different quantities, six stresses and three velocities. Each of the three SI components is a time-varying quantity, which makes both the magnitude and direction of the SI vector change in time.

The SI formula (1) is more complex than that for acoustic intensity. Each SI component consists of three terms instead of a single one because the shear stresses in solids, contrary to those in gases and liquids, cannot be disregarded. Sound intensity is thus simply a special case of (1) when shear effects vanish.

Figure 1 shows the computed vibration level and vectorial UEF of a flat rectangular $1 \text{ m} \times 0.8 \text{ m} \times$

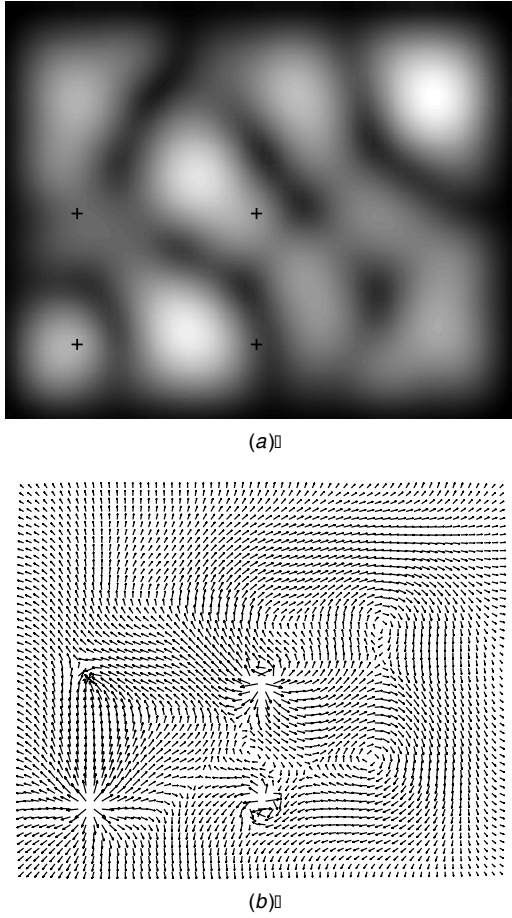

Figure 1 Vibration of a clamped plate with lossy boundaries. (a) Vibration amplitude, and (b) UEF.

9 mm steel plate with clamped but lossy boundaries. Excitation is provided at four points via connections transmitting both forces and moments to the plate. The base frequency of excitation is 50 Hz to which the harmonics 2, 3, and 4 are added. The energy flow field displays strong divergence around the excitation points, which input energy to the plate, and convergence around points, which take the energy away. Vibration propagation paths are clearly visible. The map of vibration amplitudes shown in parallel cannot reveal any of these features.

3 GOVERNING FORMULAS FOR ENERGY FLOW

Using the basic SI formula (1) the expressions for UEF or TEF can be evaluated for some simple types of structures. As a rule, a different governing formula will apply to each type of structure. This section lists governing EF formulas for rods, beams, plates, shells, and mounts. The formulas are given in terms of surface strains and velocities, that is, the quantities that can be

measured. In order to obtain a particular governing formula, some modeling is required of the internal velocity and stress-strain distribution. For structures such as rods, beams, plates, and shells, simple linear relationships can express internal quantities in terms of external ones, as long as the wavelengths of the vibration motion are much larger than the lateral dimensions of the object. The latter condition limits the applicability of the formulas presented.

It is useful to present the governing formulas in a form suitable for measurement. As stresses cannot be measured in a direct way, stress-strain relationships are used instead. For homogeneous and isotropic materials behaving linearly, such as metals, the stress-strain relationships become fairly simple. These relationships contain only two independent material constants such as Young's and shear moduli.²

3.1 Rods, Beams, and Pipes

At not too high frequencies, vibration of a rod can be decomposed in axial (longitudinal), torsional, and bending movements. If the rod is straight and of symmetric cross section, these three type of movements are decoupled. The energy flow can therefore be represented as a sum of longitudinal, torsional, and bending flows.

3.1.1 Longitudinally Vibrating Rod In longitudinal rod vibration, only the axial component of the stress in a rod differs from zero. This stress equals the product of the axial strain ϵ and the Young's modulus E . The SI distribution in the cross section is uniform. The TEF P is obtained by multiplying the intensity with the area of the cross section S :

$$P_x = -SE\epsilon_{xx}\dot{u}_x = -SE\frac{\partial u_x}{\partial x}\dot{u}_x \quad (2)$$

3.1.2 Torsionally Vibrating Rod Torsion in a rod produces shear stresses, which rise linearly from the center of the rod, as does the tangential vibration velocity. The product of the two gives the SI in the axial sense. At a distance r from the center of torsion, the axial SI is proportional to r^2 . If the rod is of a circular or annular cross section, the shear stresses are the only stresses in the rod. In such a case, the EF through the rod obtained by integrating the SI through the cross section reads

$$P = -G\Theta\frac{\partial\theta}{\partial x}\dot{\theta} \quad (3)$$

Here, Θ denotes the polar moment of inertia of the cross section, θ the angular displacement, and G the shear modulus. For a rod of annular cross section having the outer radius R_o and the inner radius R_i , the polar moment of inertia equals $\Theta = \pi(R_o^4 - R_i^4)/2$. The angular displacement derivative can then be replaced by the shear strain at the outer radius R_o , $\partial\theta/\partial x = \epsilon_{x\theta}/R_o$. Likewise, the angular velocity $\dot{\theta}$ can be replaced by the tangential velocity divided by the outer radius, \dot{u}_o/R_o .

If the rod is not of circular cross section, Eq. (3) applies still but, in addition to torsional motions, axial motions and stresses take place, which can generate the flow of energy. These depend on the shape of the cross section and should be analyzed separately in each individual case.

3.1.3 Beam Vibrating in Flexure In flexural vibration, two components of stress exist: the axial normal stress σ_{xx} and the lateral shear stress σ_{xz} . The axial stress varies linearly with distance from the neutral plane, while the variation of the shear stress depends on the cross-section shape. The axial component of particle velocity \dot{u}_x exhibits the same variation as the axial stress, while the lateral component \dot{u}_z remains constant across the beam thickness. Since the axial and lateral displacements are coupled through a simple expression $u_x = -z \partial u_z / \partial x$, two formulations of the EF are possible:

$$\begin{aligned} P_x &= \frac{JE}{\delta^2} \left(\delta \frac{\partial \varepsilon_{xx}}{\partial x} \dot{u}_z - \varepsilon_{xx} \dot{u}_x \right) \\ &= JE \left(\frac{\partial^3 u_z}{\partial x^3} \dot{u}_z - \frac{\partial^2 u_z}{\partial x^2} \frac{\partial \dot{u}_z}{\partial x} \right) \end{aligned} \quad (4)$$

where J is the area moment of inertia about the bending axis and δ the distance from the neutral plane to the outer surface, to which the stresses and axial displacement refer. The first formulation contains strains, axial, and lateral velocities³; the second one contains lateral displacements and velocities only.⁴

3.1.4 Straight Pipe At not too high frequencies, three simple types of pipe vibration dominate the pipe motion: longitudinal, torsional, and flexural. At frequencies higher than a particular limiting frequency f_{lim} other, more complex, vibrations may take place. The limiting frequency is given by

$$f_{\text{lim}} = \frac{6h}{d\sqrt{15+12\mu}} f_{\text{ring}} \quad f_{\text{ring}} = \frac{c}{\pi d} \quad (5)$$

where f_{ring} is the pipe ring frequency, h is the wall thickness, d is the mean diameter, μ is the mass ratio of the contained fluid and the pipe wall, c is the velocity of longitudinal waves in the wall, $c = \sqrt{E/\rho}$, and ρ is the pipe mass density. The three types of motion contribute independently to the total energy flow. This enables straightforward measurements.⁵ The three contributions should be evaluated separately, using the formulas (2), (3), and (4), and then be added together.

3.2 Thin Flat Plate

The normal and in-plane movements of a vibrating flat thin plate are decoupled and thus can be considered independently. The UEF can be split in two orthogonal components, as shown in Fig. 2.

3.2.1 Longitudinally Vibrating Plate In a thin plate exhibiting in-plane motion only, the intensity is constant throughout the thickness. The UEF is obtained by

Figure 2 Components of energy flow in a thin plate.

simply multiplying the intensity with the plate thickness h . The UEF component in the x direction reads³:

$$\begin{aligned} P'_x &= hD_p \left(\varepsilon_{xx} \dot{u}_x + \frac{1-\nu}{2} \varepsilon_{xy} \dot{u}_y \right) \\ &= hD_p \left(\frac{\partial u_x}{\partial x} \dot{u}_x + \frac{1-\nu}{2} \frac{\partial u_y}{\partial x} \dot{u}_y \right) \end{aligned} \quad (6)$$

where D_p is the plate elasticity modulus, $D_p = E/(1-\nu^2)$, ν being the Poisson's coefficient. An analogous expression applies for the y direction, obtained by interchanging the x and y subscripts. The expression is similar to that for a rod (2), the difference being an additional term that is due to shear stresses carrying out work on motions perpendicular to the observed direction.

3.2.2 Flexurally Vibrating Plate The stress distribution across the thickness of a thin plate vibrating in flexure is similar to that of a beam. However, the plate stresses yield twisting in addition to bending and shear. Consequently, the intensity distribution across the plate thickness is analogous to that for the beam, with the exception of an additional mechanism: that of intensity of twisting. The plate terms depend on two coordinates, x and y . The UEF in the x direction reads

$$\begin{aligned} P'_x &= \frac{Eh}{3(1-\nu^2)} \left[\frac{\partial(\varepsilon_{xx} + \varepsilon_{yy})}{\partial x} \dot{u}_z + (\varepsilon_{xx} + \nu\varepsilon_{yy}) \dot{u}_x \right. \\ &\quad \left. + \frac{1-\nu}{2} \varepsilon_{xy} \dot{u}_y \right] \end{aligned} \quad (7)$$

where ε stands for surface strain. The UEF in the y direction is obtained by an x - y subscript interchange. As for the flexurally vibrating beam, the normal component of vibration of a flexurally vibrating plate is usually of a much higher level than the in-plane component. This makes it appropriate to give the intensity expressions in terms of the normal component u_z at the cost of increasing the order of spatial derivatives involved⁴:

$$\begin{aligned} P'_x &= \frac{Eh^3}{12(1-\nu^2)} \left[\frac{\partial(\Delta u_z)}{\partial x} \dot{u}_z - \left(\frac{\partial^2 u_z}{\partial x^2} + \nu \frac{\partial^2 u_z}{\partial y^2} \right) \frac{\partial \dot{u}_z}{\partial x} \right. \\ &\quad \left. - (1-\nu) \frac{\partial^2 u_z}{\partial x \partial y} \frac{\partial \dot{u}_z}{\partial y} \right] \end{aligned} \quad (7a)$$

where Δ is a Laplacian, $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2$. The UEF formula (7a) is the one most frequently used.

3.3 Thin Shell

Due to the curvature of the shell, the in-plane and the normal motions are coupled. The UEF expressions for the shell become very complex.⁶ If the shell is either cylindrical or spherical, the expressions for the UEF along the wall of the shell are the same as for a flat plate with the addition of a curvature-dependent UEF term P'_c :

$$P'_{\text{shell}} = (P'_{\text{in-plane}} + P'_{\text{flexural}})_{\text{plate}} + P'_c \quad (8)$$

The first two terms in brackets are given by Eqs. (6) and (7). The curvature term is fairly complex and contains many terms. In the case of thin shells, it can be simplified.

3.3.1 Circular Cylindrical Shell Let the shell be positioned axially in the x direction with the local x - y - z coordinate system attached to the observation point such that y is in tangential and z in radial direction. The axial and tangential components of the simplified curvature term read

$$\begin{aligned} P'_{c,x} &\approx -\frac{Eh^3}{12(1-\nu^2)} \frac{\nu}{a} u_z \dot{u}_x \\ P'_{c,y} &\approx -\frac{Eh^3}{12(1-\nu^2)} \frac{1}{a} u_z \dot{u}_y \end{aligned} \quad (9)$$

3.3.2 Spherical Shell If the shell is thin, the curvature-dependent term is approximately equal to⁸

$$P'_{c,x} \approx -\frac{Eh^3}{12(1-\nu^2)} \frac{1+\nu}{a} u_z \dot{u}_x \quad (10)$$

In this case, the curvature terms in x and y directions are the same since the shell is centrally symmetrical about the normal to the surface.

3.4 Resilient Mount

Beams (rods), plates, and shells usually represent generic parts of builtup mechanical assemblies. The energy flow in typical builtup structures can be found by using the expressions given in the preceding sections. These expressions refer to local energy flow and can be applied to any point of the part analyzed. Resilient mounts used for vibroisolation transmit energy flow, too. As mounts usually serve as a link between vibration sources and their support, all the vibratory energy flows through mounts.

3.4.1 Unidirectional Motion of Mount Ends At low frequencies, a mount behaves as a spring. The internal force in the mount is then approximately proportional to the difference of end displacements, $F \approx \zeta(u_1 - u_2)$. The input energy flow P_{in} and that leaving the mount P_{out} can be obtained by⁹

$$\begin{aligned} P_{\text{in}} &= F \dot{u}_1 \approx \zeta(u_1 - u_2) \dot{u}_1 \\ P_{\text{out}} &= F \dot{u}_2 \approx \zeta(u_1 - u_2) \dot{u}_2 \end{aligned} \quad (11)$$

where ζ denotes the stiffness of the mount in the given direction.

3.4.2 General Motion Conditions In a general case, the movements of endpoints of a mount will not be limited to a single direction only. The direction of the instantaneous motion will change in time, while translations will be accompanied by rotations. The displacement of each endpoint can be then decomposed into three orthogonal translations and three orthogonal rotations (Fig. 3). The single internal force has to be replaced by a generalized internal load consisting of three orthogonal forces and three orthogonal moments. Each of these will depend on both end displacements, thus leading to a matrix expression of the following form:

$$\{Q\} \approx [K_1]\{u_1\} - [K_2]\{u_2\} \quad (12)$$

where $\{Q\} = \{F_x, F_y, F_z, M_x, M_y, M_z\}^T$ represents the internal generalized load vector (comprising the forces and moments), while $\{u_1\} = \{u_{x1}, u_{y1}, u_{z1}, \varphi_{x1}, \varphi_{y1}, \varphi_{z1}\}^T$ and $\{u_2\} = \{u_{x2}, u_{y2}, u_{z2}, \varphi_{x2}, \varphi_{y2}, \varphi_{z2}\}^T$ are the generalized displacement vectors of endpoints 1 and 2. Each of the stiffness matrices K in (12) contains $6 \times 6 = 36$ stiffness components that couple six displacement components to six load components. Due to reciprocity, some of the elements of K are equal, which reduces the number of cross stiffness terms.

The total energy flow through the mount reads

$$\begin{aligned} P_{\text{in}} &\approx \{Q\}^T \{\dot{u}_1\} = (\{u_1\}^T [K_1]^T - \{u_2\}^T [K_2]^T) \{\dot{u}_1\} \\ P_{\text{out}} &\approx \{Q\}^T \{\dot{u}_2\} = (\{u_1\}^T [K_1]^T - \{u_2\}^T [K_2]^T) \{\dot{u}_2\} \end{aligned} \quad (13)$$

Equation (13), giving the instantaneous energy flow entering and leaving the mount, is valid as long as the inertial effects in the mount are negligible, that is, at low frequencies. The stiffness components appearing in Eq. (12) are assumed to be constant, which corresponds to the concept of a massless mount. With increase in frequency, these simple conditions change, as described in the next section.

Figure 3 Movements and loading of a resilient element contributing to energy flow.

4 MEAN ENERGY FLOW AND FLOW SPECTRUM

The governing formulas for energy flow given in the preceding chapter refer to the instantaneous values of intensity. It is useful to operate with time-averaged values of intensity and energy flow. This value is obtained by time averaging each of the terms appearing in the given governing formula.

The terms to be averaged are, without exception, the products between two time-dependent variables. The time-averaged product of two variables, $q_1(t)$ and $q_2(t)$, can be represented in the frequency domain by the one-sided cross spectral density function of the two variables $G_{12}(\omega)$. The spectral density concept can be readily applied to the energy flow¹⁰:

$$\overline{q_1(t)q_2(t)} = \text{Re} \int_0^\infty G_{12}(\omega) d\omega \quad (14)$$

Here, the horizontal bar denotes time averaging, while Re denotes the real part of a complex variable.

Time-averaged EF represents net energy flow at the observed point. It is termed *active* because it refers to the portion of total energy flow that flows out of a given region. The remaining portion of the energy flow, which fluctuates to and fro but has zero mean value, is accordingly termed *reactive*. It is usually represented by the imaginary part of the cross spectral density of flow.

4.1 Vibration Waves and Energy Flow

Vibration can be represented in terms of waves. Such a representation is particularly simple in the case of a vibrating rod or a beam because the wave motion takes place in an axial direction only. The parameters of wave motion can be easily computed or measured.

At any frequency, the vibratory motion of a rod can be given in terms of velocity amplitudes of two waves, V_1 and V_2 , traveling along the rod in opposite directions. The TEF in the rod then equals

$$P = \frac{1}{2}C(V_1^2 - V_2^2) \quad (15)$$

with $C = S\sqrt{E\rho}$ for longitudinal vibration and $C = (\Theta/R_o^2)\sqrt{G\rho}$ for torsional vibration.

In a beam vibrating in flexure, the two traveling waves of amplitudes V_1 and V_2 are accompanied by two evanescent waves. The latter contribute to energy flow, too. The contribution of evanescent waves depends on the product of their amplitudes as well as on the difference of their phases ψ_+ and ψ_- . While the amplitudes of evanescent waves V_{e1} and V_{e2} , unlike those of traveling waves, vary along the beam, their product remains the same at any position. The phase difference between the evanescent waves is also invariant with respect to axial position. The TEF

in the beam, given in terms of vibration velocities, reads¹¹

$$P = (\rho S)^{3/4}(JE)^{1/4}\sqrt{\omega}[V_1^2 - V_2^2 - V_{e1}V_{e2}\sin(\psi_+ - \psi_-)] \quad (16)$$

4.1.1 Simplified Governing Formulas for Flexurally Vibrating Beams and Plates

At beam positions that are far from terminations, discontinuities, and excitation points, called the far field, the contribution of evanescent waves can be neglected. The notion of a far field applies to both beams and plates. The far-field range distance depends on frequency. It is approximately given for a beam by $d = (\pi/\sqrt{\omega})(JE/\rho S)^{1/4}$, where J is the area moment of inertia and S the cross-section area. For a plate, this distance is approximately $d = (\pi/\sqrt{\omega})[h^2E/12\rho(1 - \nu^2)]^{1/4}$, where h is the thickness and ν the Poisson coefficient.

The far-field plate vibration is essentially a superposition of plane propagating waves. In such regions, a simplified formula applies to the spectral density of EF in flexural motion¹²:

$$G_P = -C/\text{Im}\{G_{v_{vx}}\} \quad (17)$$

where $G_{v_{vx}}$ is the cross spectral density between the vibration velocity and its x derivative, while C is a constant depending on the cross section, mass density ρ , and Young's modulus E . For a beam $C = 2\sqrt{SJE\rho}$, for a plate $C = 0.577h^2\sqrt{E\rho/(1 - \nu^2)}$.

4.2 Energy Flow in a Resilient Mount at Higher Frequencies

As the frequency increases, the mass of the mount becomes nonnegligible. The internal forces in the mount are no longer proportional to the relative displacements of the mount; neither are these forces the same at the two terminal points. The relationship between the forces and the vibration velocities at the terminal points is frequency dependent. It is usually expressed in terms of the direct and transfer stiffness of each of the two points. Due to inevitable internal losses in the element, the input EF must be larger than the output EF.

By assuming pure translational motion in the direction of the mount axis, four dynamic stiffness components of the mount can be defined, K_{11} , K_{22} , K_{12} , and K_{21} , such that

$$K_{mn} = j\omega \frac{F_m}{V_n} e^{j\zeta_{mn}} \Big|_{V_{k \neq n} = 0} \quad m, n, k = 1, 2 \quad (18)$$

Here, F and V stand for the force and velocity amplitudes, respectively, and ζ_{mn} stands for the phase shift between the force and velocity while $j = \sqrt{-1}$. Each stiffness component K_{mn} thus becomes a complex, frequency-dependent quantity, which depends purely on mount properties. Given the end velocity amplitudes V_1 and V_2 and the phase shift between the

vibration of the points 1 and 2 φ_{12} , the TEF at the mount endpoints 1 and 2 reads

$$P_1 = \frac{1}{2\omega} [V_1^2 |K_{11}| \sin(\zeta_{11}) + V_1 V_2 |K_{12}| \sin(\zeta_{12} - \varphi_{12})]$$

$$P_2 = \frac{1}{2\omega} [V_2^2 |K_{22}| \sin(\zeta_{22}) + V_1 V_2 |K_{21}| \sin(\zeta_{21} + \varphi_{12})]$$
(19)

Due to reciprocity, the two cross stiffness components are mutually equal, $K_{21} = K_{12}$. If the mount is made symmetrical with respect to two endpoints, the direct stiffness components are equal too, $K_{11} = K_{22}$.

When the mount exhibits motion of a more general nature than simple translation in one direction, the evaluation of energy flow through the mount becomes increasingly difficult. The basic guideline for the computation of the TEF in such a case is the following:

- Establish the appropriate stiffness matrix (i.e., relationships between all the relevant forces + moments and translation + angular displacements).
- Reconstruct the force + moment vectors at the endpoints from the known motions of these points.
- The TEF is obtained as the scalar product of the resultant force vector and the translational velocity vector plus the product of the resultant moment vector and the angular velocity vector. This applies to each of the endpoints separately.

Most resilient mounts, for example, those made of elastomers, have mechanical properties that depend not only on frequency but also on static preloading, temperature, and dynamical strain. Dynamic stiffness of the mount can sometimes be modeled as a function of operating conditions.¹³ If the mount is highly nonlinear in the operating range, or if the attachments cannot be considered as points (e.g., rubber blocks of extended length, sandwiched between steel plates), the approach outlined above becomes invalid.

Figure 4 shows the total energy flow across all of the 4 resilient mounts of a 24-kW reciprocating piston compressor used in a water-chiller refrigeration unit. As the vibrations have essentially a multiharmonic spectrum, only the harmonics of the base frequency of 24 Hz are shown. Each harmonic is represented by the value of energy flow entering (dark columns) and leaving (light columns) the mounts. Absolute values are shown, to accommodate the decibel scale used. This explains seemingly conflicting results at some higher harmonics where the flow that leaves the mounts gets higher values than that entering the mounts.

5 MEASUREMENT OF ENERGY FLOW

Governing formulas for energy flow can be expressed in different ways using either stresses (strains), displacements (velocities, accelerations), or combinations

Figure 4 Energy flow through compressor mounts. (Dark columns) flow entering the mounts and (light columns) flow leaving the mounts. Absolute values are shown.

of these. As a general rule, the formulations based solely on vibration displacements (velocities, accelerations) are preferred by vibration specialists.

Each governing formula contains products of time-varying field variables that need to be measured simultaneously. Spectral representation of energy flow can be obtained by replacing product averages by the corresponding spectral densities.

The energy flow governing formulas, except in the case of resilient mounts, contain spatial derivatives of field variables. Measurement of spatial derivatives represents a major problem. In practice, the derivatives are substituted by finite difference approximations. Finite difference approximations lead to errors that can be analytically estimated and sometimes kept within acceptable limits by an appropriate choice of parameters influencing the measurement accuracy. A way of circumventing the measurement of spatial derivatives consists of establishing a wave model of the structure analyzed and fitting it with measured data. This technique is known as wave decomposition approach.^{3,14} The decomposition approach enables the recovery of all the variables entering the governing formulas.

5.1 Transducers for Measurement of Energy Flow

Measurement of energy flow requires the use of displacement (velocity, acceleration) or strain sensors or both. Structure-borne vibrations at a particular point generally consist of both normal and in-plane (tangential) components, which can be translational and/or rotational. Measurement of SI or EF requires separate detection of some of these motions without any perceptible effect from other motions. This requirement poses the major problem in practical measurements. Another major problem results from the imperfect behavior of individual transducers, which gives a nonconstant relationship between the physical quantity measured and the electrical signal that represents it. Both effects can severely degrade accuracy since the measured quantities make up the product(s) where these effects matter a lot.

5.1.1 Seismic Accelerometer An accelerometer is easy to mount and to use but shows some negative features where SI (EF) is concerned:

- *Cross sensitivity:* An accelerometer always possesses some cross sensitivity, typically up to a few percent. Nonetheless, this effect can still be significant, especially in cases where a given motion is measured in the presence of a strong component of cross motion.
- *Positioning:* Due to its finite size, the sensitivity axis of an accelerometer used for in-plane measurement can never be placed at the measurement surface. Thus, any in-plane rotation of the surface corrupts the accelerometer output. Compensation can be effected by measuring the rotation of the surface.
- *Dynamic loading:* An accelerometer loads the structure to which it is attached. This effect is of importance for SI measurement on lightweight structures.

5.1.2 Strain Gauge Strain gauges measure normal strain, that is, elongation. Shear strain at the free surface can be measured by two strain gauges placed perpendicularly to each other. Resistive strain gauges exhibit few of the drawbacks associated with accelerometers: cross sensitivity is low and the sensitivity axis is virtually at the surface of the object, due to extremely small thickness of the gauge, while dynamic loading is practically zero. However, the conventional gauges exhibit low sensitivity where typical levels of strain induced by structure-borne vibration are concerned, which means that typical signal-to-noise values could be low. Semiconductor gauges have a much higher sensitivity than the conventional type, but high dispersion of sensitivity makes the semiconductor gauges unacceptable for intensity work.

5.1.3 Noncontact Transducers Various non-contact transducers are available for the detection of structure motion such as inductive, capacitive, eddy current, light intensity, and light-modulated transducers. The majority of such transducers are of a highly nonlinear type. Optical transducers that use the interference of coherent light such as LDV (laser Doppler velocimeter) are well suited for SI work.¹⁵ The most promising, however, are optical techniques for whole-field vibration detection, such as holographic or speckle-pattern interferometric methods.¹⁶ Applications of these are limited, for the time being, to plane surfaces and periodic signals only. Another interesting approach of noncontact whole-field SI measurement of simple-shaped structures consists of using acoustical holography.^{17,18}

5.2 Transducer Configurations

In some cases of the measurement of energy flow, more than one transducer will be needed for the detection of a single physical quantity:

- When separation of a particular type of motion from the total motion is required

- When detection of a spatial derivative is required
- When different wave components need to be extracted from the total wave motion

The first case arises with beams, plates, and shells where longitudinal and flexural motions take place simultaneously. The second case occurs when a direct measurement implementation of SI or EF governing equations is performed. The third case applies to waveguides—beams, pipes, and the like—where the wave decomposition approach is used.

5.2.1 Separation of Components of Motion In a beam or a rod all three types of vibration motion, that is, longitudinal, torsional, and flexural, can exist simultaneously. The same applies to longitudinal and flexural vibrations in a flat plate. The problem here is that both longitudinal and flexural vibrations produce longitudinal motions. In order to apply intensity formulas correctly to a measurement, the origin of the motion must be identified. This can be done by connecting the measuring transducers in such a way as to suppress the effects of a particular type of motion, for example, by placing two identical transducers at opposite sides of the neutral plane and adding or subtracting the outputs from the transducers.

In the case of shells, the in-plane motions due to bending must be separated from the extensional motions before shell governing formulas can be applied. Corrections for the effect of bending, which affects longitudinal motion measured at the outer surface, apply for thin shells in the same way as for thin plates.

5.2.2 Measurement of Spatial Derivatives Formulas for energy flow contain spatial derivatives. The usual way of measuring spatial derivatives is by using finite difference concepts. The spatial derivative of a function q in a certain direction, for example, the x direction, can be approximated by the difference between the values of q at two adjacent points, 1 and 2, located on a straight line in the direction concerned:

$$\frac{\partial q}{\partial x} \approx \frac{q(x + \Delta x/2) - q(x - \Delta x/2)}{\Delta x} \quad (20)$$

The spacing Δx should be small in order to make the approximation (20) valid. The term “small” is related to the wavelength of vibration. Using the principle outlined, higher order derivatives can be determined from suitable finite difference approximations. Referring to the scheme in Fig. 5, the spatial derivatives appearing in the EF formulas can be determined from the finite difference approximations listed below.

$$\begin{aligned} \frac{\partial q}{\partial y} &\approx \frac{q_2 - q_4}{2\Delta} & \frac{\partial^2 q}{\partial x^2} &\approx \frac{q_1 - 2q_0 + q_3}{\Delta^2} \\ \frac{\partial^2 q}{\partial y^2} &\approx \frac{q_2 - 2q_0 + q_4}{\Delta^2} & \frac{\partial^2 q}{\partial x \partial y} &\approx \frac{q_5 - q_6 + q_7 - q_8}{4\Delta^2} \end{aligned} \quad (21)$$

Figure 5 Transducer configuration for measurement of spatial derivatives.

Errors in measurement of higher order derivatives, such as those appearing in the expressions for plate and shell flexural vibration, increase exponentially with the order of derivative. For these reasons, measurement of higher order spatial derivatives should be avoided. Simplified measurement techniques, such as the two-transducer method described, may seem far more suitable for practical purposes. These, however, have to stay limited to far-field conditions, that is, locations far from sources or discontinuities.

5.3 Wave Decomposition Technique

This approach is suitable for waveguides, for example, rods, beams, and pipes, where the vibration field can be described by a simple wave model in frequency domain. The velocity amplitude V_n of longitudinal or torsional (i.e., nondispersive) vibration can be represented by two oppositely propagating waves, those of

flexural (dispersive) vibration V_d by four waves:

$$V_n(x, \omega) = \sum_{i=1}^2 V_i e^{j\varphi_i} e^{j(-1)^i k x}$$

$$V_d(x, \omega) = \sum_{i=1}^4 V_i e^{j\varphi_i} e^{(-j)^i k x} \quad (22)$$

In such a representation the wave amplitudes V_i as well as the phases φ_i of these waves are unknown. The wavenumber k is supposed to be known. By measuring complex vibration amplitudes V_n at two positions, x_1 and x_2 , the unknown wave amplitudes can be easily recovered. Likewise, the measurement of complex vibration amplitudes V_d at four positions, x_1, \dots, x_4 , can recover the four related amplitudes by some basic matrix manipulations. Once these are known, the energy flow is obtained from Eq. (15) or (16).

Figure 6 shows the application of the wave decomposition technique to a 1-mm-thick steel beam. The 28-cm-long, 1.5-cm-wide beam was composed of two parts joined by a resilient joint. The spacing between measurement points was 2 cm. The measurements were done using a scanning laser vibrometer. The signal from the vibration exciter driving the beam was used as a reference to provide the phase relationship between different measurement signals that could not be simultaneously recorded. The left plot shows the amplitudes of two propagating waves while the right plot shows the TEF evaluated by using the amplitude data via Eq. (16).

Figure 6 TEF measured in a 1-mm-thick steel beam incorporating a resilient joint. (a) Amplitudes of propagating flexural waves: thick line, positive direction; thin line, negative direction. (b) TEF.

5.4 Measurement Errors

Measurements of energy flow are very sensitive to various types of errors. An electrical signal from the transducer may be subjected to distortion and noise, which can greatly affect the resulting intensity readings. Equally damaging can be the inaccurate positioning and cross sensitivity of transducers.

5.4.1 Instrumentation Error The most significant source of signal distortion where SI (EF) is concerned is the phase shift between the physical quantity measured and the conditioned electrical signal that represents it. This effect becomes particularly significant in connection with finite difference representation of field variables.¹⁹ It can be shown that the error due to phase shift $\Delta\phi$ in the measurement of spatial derivatives has the order of $1/(k\Delta)^n$, where Δ is the distance between transducers and n the derivative order.

To keep the phase mismatch error small, the instrumentation phase matching between channels must be extremely good because the product $k\Delta$ has itself to be small in order to make the finite difference approximation valid.

Another important error that can affect measurement accuracy can be caused by the transducer mass loading.²⁰ The transducer mass should be kept well below the value of the structural apparent mass.

5.4.2 Finite Difference Convolution Error By approximating spatial derivatives with finite differences, systematic errors are produced that depend on the spacing between the transducers. Thus, the finite difference approximation of the first spatial derivative will produce an error equal to

$$\varepsilon \approx -\frac{1}{24}(k\Delta)^2 \quad (23)$$

This error is seen to be negative: That is, the finite difference technique underestimates the true value. The finite difference error of the second derivative is approximately twice the error of the first derivative. The errors of higher order derivatives rise in proportion to the derivative order, in contrast to the instrumentation errors, which exhibit an exponential rise.

5.4.3 Wave Decomposition coincidence error The technique of wave decomposition is essentially a solution to an inverse problem. At particular "coincidence" frequencies, which occur when the transducer spacing matches an integer number of half the wavelength, the solution is badly conditioned, making the error rise without limits. This error can be avoided by changing the spacing and repeating the measurements.

CHAPTER 17

STATISTICAL ENERGY ANALYSIS

Jerome E. Manning
Cambridge Collaborative, Inc.
Cambridge, Massachusetts

1 INTRODUCTION

Statistical energy analysis (SEA) is commonly used to study the dynamic response of complex structures and acoustical spaces. It has been applied successfully in a wide range of industries to assist in the design of quiet products. SEA is most useful in the early stages of design when the details of the product are not known and it is necessary to evaluate a large number of design changes. SEA is also useful at high frequencies where the dynamic response is quite sensitive to small variations in the structure and its boundary conditions.

A statistical approach is used in SEA to develop a prediction model. The properties of the vibrating system are assumed to be drawn from a random distribution. This allows great simplifications in the analysis, whereby modal densities, average mobility functions, and energy flow analysis can be used to obtain response estimates and transfer functions.

Statistical energy analysis combines statistical modeling with an energy flow formulation. Using SEA, the energy flow between coupled subsystems is defined in terms of the average modal energies of the two subsystems and coupling factors between them. Equations of motion are obtained by equating the time-average power input to each subsystem with the sum of the power dissipated and the power transmitted to other subsystems. Over the past 10 years SEA has grown from an interesting research topic to an accepted design analysis tool.

2 STATISTICAL APPROACH TO DYNAMIC ANALYSIS

Earlier chapters of this handbook have presented a variety of techniques to study the dynamic response of complex structural and acoustical systems. By and large, these techniques have used a deterministic approach. In the analytical techniques, it has been assumed that the system being studied can be accurately defined by an idealized mathematical model. Techniques based on the use of measured data have assumed that the underlying physical properties of the system are well defined and time invariant. Although the excitation of the system was considered to be a random process in several of the earlier sections, the concept that the system itself has random properties was not pursued.

The most obvious source of randomness is manufacturing tolerances and material property variations. Although variations in geometry may be small and have a negligible effect on the low-frequency dynamics of the system, their effect at higher frequencies cannot be neglected. Another source of randomness is uncertainty in the definition of the parameters needed to

define a deterministic model. For example, the geometry and boundary conditions of a room will change with the arrangement of furnishings and partitions. Vehicles will also change due to different configurations of equipment and loadings. Finally, during the early phases of design, the details of the product or building being designed are not always well defined. This makes it necessary for the analyst to make an intelligent guess for the values of certain parameters. If these parameters do not have a major effect on the response being predicted, the consequences of a poor guess are not serious. On the other hand, if the parameters do have a major effect, the consequences of a poor guess can be catastrophic. Although deterministic methods of analysis have the potential to give exact solutions, they often do not because of errors and uncertainties in the definition of the required parameters.

The vibratory response of a dynamic system may be represented by the response of the modes of vibration of the system. Both theoretical and experimental techniques to obtain the required mode shapes and resonance frequencies exist. A statistical approach will now be followed in which resonance frequencies and mode shapes are assumed to be random variables. This approach will result in great simplifications where average mobility functions and power inputs from excitation sources can be defined simply in terms of the modal density and structural mass or acoustical compliance of the system. Modal densities in turn can be expressed in terms of the dimensions of the system and a dispersion relation between wave number and frequency.

If the properties describing a dynamic system can be accurately defined, the modes of the system can be found mathematically in terms of the eigenvalues and eigenfunctions of a mathematical model of the system, or they can be found experimentally as the resonance frequencies and response amplitudes obtained during a modal test. The availability of finite element models and computer software makes it possible today to determine the modes of very complex and large structures. Although it might be argued that the computational cost to determine a sufficient number of modes to analyze acoustical and structural systems at high frequencies is too high, that cost is dropping each year with the development of faster and less expensive computers. Thus, many vibration analysts believe that analysis based on modes determined from a finite element model can provide them with the answers they need. Similarly, many engineers who are more inclined toward the use of measured data believe that analysis based on modes determined from a modal test will suffice.

Figure 1 Drive point conductance and susceptance for a typical structure.

The accuracy of a modal analysis depends on the accuracy with which the modal parameters can be determined and on the number of modes that are included in the analysis. Since the modes form a mathematically complete set of functions, a high degree of accuracy can be obtained by including a large number of modes in the analysis. In practice, the accuracy with which the modal parameters can be determined decreases for the higher order modes. Thus, the accuracy of the modal analysis depends to a large extent on the number of modes needed to describe the vibration of the system. At low frequencies, for lightly damped systems, the response can be accurately described in terms of the response of a few modes. On the other hand, at high frequencies and for highly damped systems, a large number of modes are required, and the accuracy of the modal analysis decreases. In this case, a statistical description of the system is warranted. Using a statistical description avoids the need for an accurate determination of the resonance frequencies and mode shapes, thereby eliminating the main source of error in the modal analysis. Of course, in using a statistical description, the ability to determine the exact response at specific locations and frequencies is lost. Instead, a statistical description of the response is obtained.

2.1 Mobility Formulation

To illustrate the use of modal analysis and the application of a statistical approach, the response of a linear system to a point excitation with harmonic $e^{j\omega t}$ time dependence is considered. For a structural system, the ratio of the complex amplitude of the response velocity to the complex amplitude of the excitation force is defined as the point mobility for the system. A transfer mobility is used if the location of the response point is different than that of the excitation point. A drive point mobility is used if the locations of the response and drive points are the same. The drive point mobility at coordinate location x can be written as a

summation of modal responses,

$$Y_{pt}(x, \omega) = \sum_{i=1}^{\infty} \frac{1}{M_i} \frac{j\omega\psi_i^2(x)}{(\omega_i^2 - \omega^2) + j\omega\omega_i\eta_i} \quad (1)$$

where $Y_{pt}(x, \omega)$ is the drive point mobility for the structure, M_i is the modal mass, $\psi_i(x)$ is the mode shape for the i th mode, ω is the radian frequency of excitation, ω_i is the resonance frequency of the i th mode, η_i is the damping loss factor, j equals the square root of -1 , and the summation is over all modes of the system. The mobility consists of a real part—the conductance—and an imaginary part—the susceptance. The conductance is often of greater interest since the product of the conductance and the mean-square force is the input power to the system. The conductance and susceptance for a typical lightly damped system are shown in Fig. 1.

For light damping, the conductance as a function of frequency shows a large peak at each resonance frequency. The amplitude of the peak is governed by the damping and by the value of the mode shape at the drive point. Since the resonance frequencies and mode shapes are assumed to be random, the conductance as a function of frequency is analogous to a random time series of pulses. Fortunately, the statistics of such a random process has been extensively studied.

2.1.1 Frequency Averages A frequency-averaged conductance is found by integrating the real part of the mobility over frequency and dividing by the bandwidth:

$$\langle G_{pt}(x, \omega) \rangle_{\Delta\omega} = \frac{1}{\Delta\omega} \int_{\Delta\omega} \text{real}\{Y_{pt}(x, \omega)\} \Delta\omega \quad (2)$$

where $\langle \rangle$ signifies an average, $\text{real}\{ \}$ signifies the real part of a complex number, and the integral is over the frequency band, $\Delta\omega$. For any particular frequency band, the average conductance is largely determined by the number of modes with resonance frequencies

within the band. For light damping, the contribution to the integral in Eq. (2) from a single mode with a resonance frequency within the band is approximately $(\pi/2)\psi_i^2/M_i$. If the resonance frequency of the mode is outside of the band, $\Delta\omega$, the contribution to the integral is very small and can be ignored. Thus, the frequency-averaged conductance is given by

$$\langle G_{\text{pt}}(x, \omega) \rangle_{\Delta\omega} = \frac{1}{\Delta\omega} \frac{\pi}{2} \sum_{\substack{i \\ \text{modes} \\ \text{in } \Delta\omega}} \frac{\psi_i^2(x)}{M_i} \quad (3)$$

where the summation is over all modes with resonance frequencies in the band. Note that the frequency-averaged conductance does not depend on the precise values for the resonance frequencies or the damping, but only on the number of modes within the band and their mode shapes at the drive point.

2.1.2 Spatial Averages The statistical approach can be extended one step further by averaging the conductance over the spatial extent of the system. For a homogeneous system, the spatial-average value of the mode shape squared is equal to the modal mass divided by the physical mass of the system, M_i/M . Thus, the drive point conductance averaged both over a band of frequencies and over the spatial extent of the system is given by

$$\langle G_{\text{pt}}(x, \omega) \rangle_{\Delta\omega, x} = \frac{\pi}{2M} \frac{N_{\Delta\omega}}{\Delta\omega} \quad (4)$$

where $N_{\Delta\omega}$ is the number of modes with resonance frequencies in the band $\Delta\omega$ —the “resonant mode count”—and M is the physical mass of the structure. Equation (4) applies only to homogeneous structures. However, it can also be used for the general case, if we replace M in Eq. (4) by the dynamic mass, M_d , where

$$M_d(\omega) = \frac{1}{N_{\Delta\omega}} \sum_{\substack{i \\ \text{modes} \\ \text{in } \Delta\omega}} \frac{\langle \psi_i^2(x) \rangle_x}{M_i} \quad (5)$$

The definition of a dynamic mass allows the expression given in Eq. (4) to be used for the average conductance of both homogeneous structures and nonhomogeneous structures, such as framed plates and structures loaded with components.

2.1.3 Acoustical Systems The formulation above is for a structural system in which the equations of motion are formulated in terms of a response variable such as displacement. For an acoustic system, the equations of motion are typically formulated in terms of pressure, a stress variable. In this case, a similar formulation can be carried out. However, the acoustical

resistance—pressure divided by volume velocity—is obtained rather than the conductance, and the structural mass is replaced by the bulk compliance of the acoustical space,

$$\langle R_{\text{pt}}^A(x, \omega) \rangle_{\Delta\omega, x} = \frac{\pi}{2} \frac{N_{\Delta\omega}}{\Delta\omega} \frac{1}{C_a} \quad (6)$$

where R_{pt}^A is the point acoustical resistance for the acoustical space and C_a is the bulk compliance of the space ($V/\rho c^2$ for a space with rigid walls).

2.1.4 Ensemble Averages An ensemble-averaged conductance is found by averaging the real part of the mobility over a large number of individual products drawn from a random distribution. For example, an ensemble of products may be defined as the vehicles coming off a production line. Alternatively, an ensemble may be defined as the vehicles of a specific model with random configurations for passenger load, interior trim, and road conditions. The ensemble average has the advantage that it can be useful both for random excitation and for single frequency excitation.

If an ensemble of systems is defined such that the resonance frequencies are distributed as a Poisson random process and the mode shapes are uniformly distributed, the ensemble average is given by

$$\langle G_{\text{pt}}(x, \omega) \rangle_{\text{ens}} = \frac{\pi}{2} \frac{n(\omega)}{M_d} \quad (7)$$

where $n(\omega)$ is the modal density for the system—the ensemble-average number of modes per unit radian frequency.

It is common in SEA to assume that ensemble averages are equal to frequency averages. This is analogous to the ergodic assumption for a random time series in which ensemble averages are equal to time averages. The validity of the SEA ergodic assumption depends on the underlying validity of the assumed probability distributions for resonance frequencies and mode shapes. An extensive amount of work is required to validate these distributions. Thus, the SEA ergodic assumption is often accepted as a “best available” estimate. It should, however, be used with caution.

The susceptance or imaginary part of the mobility can also be determined from a modal summation. However, since the imaginary part of each term in the summation exhibits both positive and negative values, the number of terms that must be included in the summation to obtain a good estimate of the susceptance is much greater than were required to obtain a good estimate of the average conductance.

2.2 Modal Density

The previous section shows how the use of a statistical description of a dynamic system can lead to a great simplification in the determination of the average structural conductance or acoustical resistance. The exact resonance frequency and mode shape for each

individual mode are no longer needed. Instead, the resonant mode count or modal density can be used. The distinction between these two variables is often quite subtle. The term *mode count* is used to describe the number of modes with resonance frequencies within a given frequency band. The modal density, on the other hand, is a mathematical quantity that gives a statistical estimate of the average number of resonant modes per unit frequency for an ensemble of systems. If we define an ensemble of system for which the geometry and material parameters vary randomly within manufacturing tolerances or design limits, the mode count will vary from system to system within the ensemble. The average mode count over the ensemble can be estimated from the modal density:

$$N_{\Delta\omega} = \int_{\omega_1}^{\omega_2} n(\omega) d\omega \quad (8)$$

where ω_1 and ω_2 are the lower and upper frequencies of the band, $\Delta\omega$. In many cases the modal density will be a fairly smooth function of frequency. The average mode count can then be obtained simply as the product of the modal density at the band center frequency and the frequency bandwidth.

2.2.1 Asymptotic Modal Densities In most cases, the mode count or modal density can be determined analytically using asymptotic modal densities that are valid at high frequencies where many resonant modes exist even in narrow bands of frequency. The general use of these asymptotic modal densities to obtain the mode count has led to the idea that statistical modeling can only be used at high frequencies. This is indeed a misconception. As long as correct values are used for the modal density and the dynamic mass, the statistical modeling can be extended to low frequencies where the number of modes is small. However, at these low frequencies the variance of the estimates may become quite large, so that the average value is not a good estimate for any individual structure.

One-Dimensional System The modes of a one-dimensional system have mode shapes that are functions of a single spatial coordinate. For a system with uniform properties, the mode shapes at interior positions away from any boundary are in the form of a sinusoid,

$$\psi_i(x) = A_i \sin(k_i x + \varphi_i) \quad (9)$$

where k_i is a wavenumber describing the rate of variation of the mode shape with the spatial coordinate, x , and φ_i is a spatial phase factor that depends on boundary conditions. The wavenumber for a mode is related to the number of half-wavelengths within the length of the system,

$$k_i = \frac{\pi}{L}(i + \delta) \quad (10)$$

where L is the length of the system, i is an integer, and δ is a small constant, $(-\frac{1}{2} \leq \delta \leq \frac{1}{2})$ whose value

Figure 2 Wavenumber space for a one-dimensional system.

depends on the boundary conditions at each end of the system.

The modes can be represented graphically in wavenumber space. For a one-dimensional system, wavenumber space is a single axis. Each mode can be represented by a point along the axis at the value k_i , as shown in Fig. 2. If the value of δ is constant from mode to mode, as would be the case for clamped or free boundary conditions, the spacing between modes in wavenumber space, Δk , is simply the ratio π/L . If on the other hand, the value of δ is random due, for example, to a random boundary condition, the average spacing between modes is also π/L . Although the exact position of a mode in wavenumber space depends on the value of δ , each mode will “occupy” a length of the wavenumber axis defined by the average spacing, Δk .

To determine the modal density, a relationship between wavenumber and frequency is needed. This relationship is the dispersion relation or characteristic equation for the system. For a simple one-dimensional acoustical duct the dispersion relation is $k = \omega/c$, where c is the speed of sound. For bending deformations of a one-dimensional beam (without shear deformations or rotational inertia) the dispersion relation is $k^4 = \omega^2 m/EI$, where m is the mass per unit length, E is Young’s modulus for the material, and I is the bending moment of inertia. The dispersion relation allows mapping of the frequency range, $\Delta\omega$, to the corresponding wavenumber range, Δk . The average value of the mode count is then obtained by dividing Δk by $\Delta\omega$. The modal density can now be written as the limit,

$$n(\omega) = \lim_{\Delta\omega \rightarrow 0} \frac{\Delta k}{\Delta\omega} \frac{1}{\delta k} \quad (11)$$

The ratio $\Delta k/\Delta\omega$, in the limit as the frequency range approaches zero, becomes the derivative of the wavenumber with respect to frequency. This derivative is the inverse of $d\omega/dk$, which is the group speed for the system. Thus, the modal density for the general one-dimensional system becomes

$$n(\omega) = \frac{L}{\pi c_g} \quad (12)$$

The modal density of the general one-dimensional system is simply related to the length of the system and the group speed. In this asymptotic result, which becomes exact as the number of modes increases, boundary conditions are not important. For the lower order modes, it is possible to correct the modal density for specific types of boundary conditions. However, the increase in accuracy may not be worth the effort.

Figure 3 Wavenumber space for a two-dimensional system.

The general result shows that the modal density depends on the group speed. Thus, the modal density of a one-dimensional acoustical lined duct should take into account the effect of the lining on the group speed. If the acoustical media is a fluid, the wall compliance can have a significant effect on the group speed and should be considered.

Two-Dimensional System The modes of a two-dimensional system have mode shapes that vary along two spatial coordinates. Like the one-dimensional system, the modes of the two-dimensional system can be represented graphically in wavenumber space. However, wavenumber space becomes a plane defined by two axes. Each mode can be represented by a point on the plane, so that the modes of the system can be represented by a lattice of points as shown in Fig. 3. For a rectangular system, the lattice forms a rectangular grid of points. The average spacing between the points along the k_x axis is π/L_x , and the spacing between the points along the k_y axis is π/L_y , where L_x and L_y are the dimensions of the system. Thus, a mode occupies a small area in wavenumber space equal to π^2/A , where A is the area of the panel.

The dispersion relation for a two-dimensional system relates the frequency to the two wavenumber components, k_x and k_y . For a simple rectangular acoustical layer, the dispersion relation is $k_x^2 + k_y^2 = \omega^2/c^2$, where c is the speed of sound. For bending deformations of a rectangular plate (without shear deformations or rotational inertia) the dispersion relation is $(k_x^2 + k_y^2)^2 = \omega^2 m/EI'$, where m is the mass per unit area and I' is the bending moment of inertia of the plate. The dispersion relation allows lines of constant frequency to be drawn in wavenumber space for the upper and lower frequencies of the band, $\Delta\omega$. For the simple systems above, these lines are quarter-circles forming an annular region as shown

in Fig. 3. The average value of the mode count is obtained by dividing the area of this region by the area occupied by a single mode. The modal density can now be written as the limit

$$n(\omega) = \lim_{\Delta\omega \rightarrow 0} \frac{\Delta k}{\Delta\omega} \frac{kA}{2\pi} \quad (13)$$

where $k^2 = k_x^2 + k_y^2$.

The modal density for the general two-dimensional system becomes

$$n(\omega) = \frac{kA}{2\pi c_g} \quad (14)$$

Both the wavenumber and the group speed can be found from the dispersion relation.

The formulation of modal density using wavenumber space allows extension of the results to more complicated systems. For example, the modal density for bending modes of a fluid-loaded plate can be obtained by adjusting the group speed to account for the fluid loading. Similarly, the modal density for bending modes, including the effects of transverse shear deformations and rotary inertia, can be obtained by adjusting the group speed to account for these effects. The modal densities for cylindrical shells and orthotropic plates can be obtained using wavenumber space. For these cases, however, the lines of constant frequency will not be circular.

Three-Dimensional System The modes of a three-dimensional system have mode shapes that vary along three spatial coordinates. In this case, wavenumber space becomes a volume defined by three axes. Like the one-dimensional and two-dimensional systems, each mode can be represented by a point in wavenumber space, so that the modes of the system form a lattice of points in three dimensions. Each mode occupies a small volume in wavenumber space equal to π^3/V , where V is the volume of the system. The exact location of the mode within this volume will depend on the exact boundary conditions.

The dispersion relation for the three-dimensional system gives the frequency as a function of three wavenumbers. For a uniform acoustical space the dispersion relation is

$$\omega = c\sqrt{k_x^2 + k_y^2 + k_z^2} \quad (15)$$

where c is the speed of sound. The dispersion relation allows two-dimensional surfaces of constant frequency to be drawn in wavenumber space. The average cumulative mode count can now be obtained by dividing the total volume under these surfaces by the average volume occupied by a single mode. The dispersion relation for the uniform acoustical space results in spherical surfaces with a volume of $k^3/2$ (one-eighth sphere with radius k). Each mode occupies

a volume equal to π^3/V , so that the cumulative mode count becomes

$$N(\omega) = \frac{k^3 V}{6\pi^2} \quad (16)$$

The modal density is found from the derivative of the cumulative mode count:

$$n(\omega) = \frac{k^2 V}{2\pi^2 c_g} \quad (17)$$

The asymptotic modal density of the general three-dimensional space gives an accurate estimate of the mode count at high frequencies where many modes occur. It can also be used at lower frequencies as the ensemble average for systems with random boundary conditions. In room acoustics, the walls are commonly assumed to be rigid. In this case corrections to the asymptotic modal density can be introduced that improve the accuracy of the mode count at low frequencies. However, these corrections are only valid for a space in which the assumption of rigid walls is valid. Such an assumption would not be valid, for example, for a fluid-filled tank.

Table 1 provides a summary of the asymptotic modal densities and cumulative mode counts.

2.2.2 Finite Element Modeling Finite element models show great potential as a means to determine the correct mode count for complex structures and acoustical spaces at lower frequencies. Although these models may lose some accuracy in defining the resonance frequencies of the higher order modes, their use to determine the number of modes within defined frequency bands is justified. Two procedures can be used for determining a mode count from a finite element model. In the first an eigenvalue analysis is used to obtain the resonance frequencies. The mode count is obtained by dividing the frequency range of interest into bands and counting the number of resonance frequencies in each band. In the second technique, the resonance frequencies are used to determine the frequency spacing between modes. The average frequency spacing is found by averaging over a set number of spacing intervals rather than over a set frequency band. Finally, the modal density is

obtained from the inverse of the average spacing. Although the first technique is commonly used, the second technique is preferred, since it provides an estimate of the average modal density with a constant statistical accuracy.

In SEA the modes of a structural element are often subdivided into groups of modes with similar properties. For example, the modes of a plate element may be divided into *bending* and *in-plane* subsystems. When using a finite element model to determine modal densities some type of sorting based on mode shape may be required. For thin structural elements the number of bending modes in a band of frequency greatly outnumbers the in-plane compression and shear modes. It is then reasonable to use the modal density from the finite element model to determine the modal density for the bending subsystem. An example is shown in Fig. 4. In this example the modes for a section of the floor of a passenger vehicle are determined for different boundary conditions and used to obtain the modal density for the floor SEA bending subsystem.

Engineering judgment is needed to decide whether to use the modal density for a single boundary condition or to assume a random boundary condition and average the modal densities obtained from the finite element model over the different boundary conditions. The average over boundary conditions is often a more reliable estimate.

3 SEA ENERGY FLOW METHOD

Since its introduction in the early 1960s, statistical energy analysis, or SEA as it is commonly called, has gained acceptance as a method of analysis for structural-acoustical systems.¹ SEA draws on many of the fundamental concepts from statistical mechanics, room acoustics, wave propagation, and modal analysis.²⁻⁹ At first, SEA appears to be a very simple method of analysis. However, because of the diversity of concepts used in formulating the basic SEA equations, the method quickly becomes very complex. For this reason, analysts have recommended caution in using SEA. However, when used properly, SEA is a powerful method of vibration and acoustical analysis.

In SEA, the system being analyzed is divided into a set of coupled subsystems. Each subsystem represents a group of modes with similar characteristics. The SEA subsystems can be considered to be "control volumes" for vibratory or acoustic energy flow. Under steady-state conditions, the time-average power input to a subsystem from external sources and from other connected subsystems must equal the sum of the power dissipated within the subsystem by damping and the power transmitted to the connected subsystems.

Consider, for example, a piece of machinery located within an enclosure in a large equipment room as shown in Fig. 5. The noise in the equipment room due to operation of the machine is of concern. A simple SEA model for this problem is shown in Fig. 6. In this model three subsystems are used: one for

Table 1 Cumulative Mode Count and Modal Density for Homogeneous Subsystems

Subsystem	Cumulative Mode Count $N(\omega)$	Modal Density $n(\omega)$
One dimensional	$\frac{kL}{\pi}$	$\frac{L}{\pi c_g}$
Two dimensional	$\frac{k^2 A}{4\pi}$	$\frac{kA}{2\pi c_g}$
Three dimensional	$\frac{k^3 V}{6\pi^2 c_g}$	$\frac{k^2 V}{2\pi^2 c_g}$

Figure 4 Modal density from finite element analysis.

Figure 5 Machinery noise problem.

the acoustic modes of the interior space within the enclosure, one for bending modes of the enclosure walls, and one for the acoustic modes of the exterior space in the equipment room. The airborne and structure-borne noise from the machine are specified as power inputs to the model. The input power to the enclosure acoustical space, W_a^{in} , is taken to be the airborne noise radiated by the machine, which can be determined using acoustic intensity measurements. The input power to the enclosure wall, W_s^{in} , is determined from the vibration of the machine at its attachment to the enclosure base. The time-average power dissipated within each subsystem is indicated by the terms W_a^{diss} , W_s^{diss} , and W_r^{diss} .

Following the usual definition of the damping loss factor, the time-average power dissipated within the subsystem can be written in terms of the time-average

Figure 6 Simple three-element SEA model of equipment enclosure.

energy of the system and the radian frequency of vibration:

$$W_s^{\text{diss}} = \omega \eta_{s;\text{diss}} E_s \quad (18)$$

where ω is the radian frequency (typically, a one-third octave-band center frequency), $\eta_{s;\text{diss}}$ is the damping loss factor for subsystem s , and E_s is the time-average energy for subsystem s .

The energy transmitted between the connected subsystems can also be assumed to be proportional to the energy in each system. By analogy to the dissipated power, the factor of proportionality for transmitted power is called the coupling loss factor. However, since energy flow between the two systems can be in either direction, two coupling loss factors must be identified, so that the net energy flow between two connected subsystems is given by

$$W_{a;s}^{\text{trans}} = \omega \eta_{a;s} E_a - \omega \eta_{s;a} E_s \quad (19)$$

where $\eta_{a;s}$ and $\eta_{s;a}$ are the coupling loss factors between subsystem a and s and between s and a .

These two coupling loss factors are not equal. A power balance can now be performed on each subsystem to form a set of linear equations relating the energies of the subsystems to the power inputs:

$$\omega \begin{bmatrix} \eta_{a;d} + \eta_{a;s} + \eta_{a;r} & -\eta_{s;a} \\ -\eta_{a;s} & \eta_{s;d} + \eta_{s;a} + \eta_{s;r} \\ -\eta_{a;r} & -\eta_{s;r} \\ -\eta_{r;a} \\ -\eta_{r;s} \\ \eta_{r;d} + \eta_{r;a} + \eta_{r;s} \end{bmatrix} \begin{bmatrix} E_a \\ E_s \\ E_r \end{bmatrix} = \begin{bmatrix} W_a^{\text{in}} \\ W_s^{\text{in}} \\ W_r^{\text{in}} \end{bmatrix} \quad (20)$$

Note that the subscript notation typically used in SEA is not conventional matrix notation. Also note that the loss factor matrix is not symmetric.

3.1 SEA Reciprocity

The coupling loss factors used in SEA are generally not reciprocal, that is, $\eta_{s;r} \neq \eta_{r;s}$. If it is assumed, however, that the energies of the modes in a given subsystem are equal—at least within the concept of an ensemble average—and that the responses of the different modes are uncorrelated, a reciprocity relationship can be developed. The assumptions for this relationship are more restrictive than required for a general statement of reciprocity, so that the term SEA reciprocity should be used.

Statistical energy analysis reciprocity requires that the coupling loss factors between two subsystems be related by the modal densities:

$$n(\omega)_s \eta_{s;r} = n(\omega)_r \eta_{r;s} \quad (21)$$

Using this relationship, a new coupling factor, β , can be introduced that allows the energy balance equations to be written in a symmetric form:

$$\begin{bmatrix} \beta_{a;d} + \beta_{a;s} + \beta_{a;r} & -\beta_{a;s} \\ -\beta_{a;s} & \beta_{s;d} + \beta_{s;a} + \beta_{s;r} \\ -\beta_{a;r} & -\beta_{s;r} \\ \beta_{r;d} + \beta_{r;a} + \beta_{r;s} \end{bmatrix} \begin{bmatrix} E_a/n(\omega)_a \\ E_s/n(\omega)_s \\ E_r/n(\omega)_r \end{bmatrix} = \begin{bmatrix} W_a^{\text{in}} \\ W_s^{\text{in}} \\ W_r^{\text{in}} \end{bmatrix} \quad (22)$$

where

$$\beta_{s;r} = \omega \eta_{s;r} n(\omega)_s = \omega \eta_{r;s} n(\omega)_r = \beta_{r;s} \quad (23)$$

The ratio of total energy to modal density has the units of power and can be called *modal power*.

3.2 Coupling Loss Factor Measurement

The coupling loss factors or coupling factors cannot be measured directly. However, a power injection technique can be used to infer the coupling factor from measured values of power input and

response energy. Using this technique each subsystem is excited in turn with a unit power input, and the response energy of the subsystems is measured to form a matrix of measured energies. Each column in the matrix corresponds to the measured response energies when one subsystem is excited. For example, the second column contains the measured energies when the second subsystem is excited. The coupling loss factor matrix is determined by inverting the matrix of measured subsystem energies:

$$[\eta] = [E]^{-1} \quad (24)$$

The off-diagonal terms are the negative values of the coupling loss factors, while the sum of terms for each row give the damping loss factors. This measurement technique has been successfully used to “measure” in situ coupling and damping loss factors. However, errors in the energy measurement can result in large errors in the measured loss factors. Systems containing highly coupled subsystems will result in energy matrices that are poorly conditioned since two or more columns will be nearly equal. Thus, the success of the measurement technique requires careful identification of the subsystems. The best results are obtained for light coupling, when the coupling loss factors are small compared to the damping loss factors, so that the loss factor matrix is diagonally dominant.

The measurement of subsystem energy is particularly difficult for subsystems with in-plane compression and shear modes. Because of the high stiffness of the in-plane modes a small amount of motion results in a large amount of energy. The measurement of subsystem energy is also difficult for subsystems in which the mass is nonuniformly distributed. For these subsystems an effective or dynamic mass must be determined at each measurement point.

3.3 Coupling Loss Factor Theory

Coupling loss factors can be predicted analytically using wave and mode descriptions of the subsystem vibrations. Waves are used when the number of dimensions of the subsystem is greater than the number of dimensions of the connection: for example, a beam connected at a point, a plate connected at a point or along a line, and an acoustical space connected at a point, line, or area. Modes are used when the number of dimensions of the subsystem is equal to the number of dimensions of the connection: for example, a beam connected along a line and a plate connected over an area.

When a wave description can be used for all subsystems at the connection, the coupling loss factor between subsystems can be written in terms of a power transmission coefficient. For a point connection between beams, the coupling factor between subsystem s and subsystem r can be written

$$\beta_{s;r} = \omega \eta_{s;r} n_s(\omega) = \frac{1}{2\pi} \tau_{s;r} \quad (25)$$

where $\tau_{s,r}$ is the power transmission coefficient. The power transmission coefficient must take into account energy transmitted by all degrees of freedom at the connection: three translational degrees of freedom and three rotational degrees of freedom. For a point connection with a single degree of freedom (all other degrees of freedom are constrained), the transmission coefficient is given by

$$\tau_{s,r} = \frac{4R_s R_r}{|Z_j|^2} \quad (26)$$

where R is the subsystem resistance (real part of the impedance) for the unconstrained degree of freedom and Z_j is the junction impedance—the sum of the impedances of all subsystems connected at the point. The coupling factor given by Eqs. (25) and (26) can also be used for two- and three-dimensional subsystems connected at a point with a single degree of freedom, as long as the correct impedances are used. For point connections with multiple degrees of freedom, an estimate of the coupling factor can be obtained by summing the power transmission coefficients for each degree of freedom.

The coupling factor between two-dimensional subsystems connected along a line of length L can also be written in terms of a power transmission coefficient. However, for this case an integration must be performed over all angles of incidence. The coupling factor is given in terms of the angle-averaged transmission coefficient as

$$\beta_{s,r} = \omega \eta_{s,r} n_s(\omega) = \frac{1}{2\pi} \frac{k_s L}{\pi} \overline{\tau_{s,r}} \quad (27)$$

where k_s is the wavenumber of the source subsystem and $\overline{\tau_{s,r}}$ is given by

$$\overline{\tau_{s,r}} = \frac{1}{2} \int_{-\pi/2}^{+\pi/2} \tau_{s,r}(\theta_s) \cos(\theta_s) d\theta_s \quad (28)$$

and θ_s is the angle of incidence for a wave in the source subsystem. The parameter $k_s L/\pi$ is the effective number of points for the line connection. For a line connection, the power transmission coefficient must take into account the energy transmitted by 4 degrees of freedom: three translational and one rotational. For a single degree of freedom, the transmission coefficient for an incident angle, θ_s , can be expressed in terms of the line impedances of the source and receiver subsystems as

$$\tau_{s,r}(\theta_s) = \frac{4R_s(k_t)R_r(k_t)}{|Z_j(k_t)|^2} \quad (29)$$

where k_t is the trace wavenumber given by $k_s \cos(\theta_s)$, and $R(k_t)$ is the real part of the line impedance for the unconstrained degree of freedom.

The formulation above can also be used to predict the coupling loss factor between three-dimensional subsystems coupled along a line, if the integration is performed over all solid angles of incidence. For this case, the angle-averaged transmission coefficient is written as

$$\overline{\tau_{s,r}} = \int_{-\pi/2}^{+\pi/2} \tau_{s,r}(\theta_s) \sin(\theta_s) \cos(\theta_s) d\theta_s \quad (30)$$

For an area connection between three-dimensional subsystems, the coupling factor is given in terms of the angle-averaged transmission coefficient as

$$\beta_{s,r} = \omega \eta_{s,r} n_s(\omega) = \frac{1}{2\pi} \frac{k_s^2 S}{4\pi} \overline{\tau_{s,r}} \quad (31)$$

where S is the area of the connection. The effective number of points for the area connection is given by the parameter, $k_s^2 S/4\pi$.

When the number of dimensions of a subsystem is equal to the number of dimensions of the coupling, modes are used to calculate the coupling loss factor. For example, the coupling loss factor between a two-dimensional system such as a plate or shell and a three-dimensional system such as an acoustical space is obtained by calculating the radiation efficiency for each mode of the plate, and averaging over all modes with resonance frequencies in the analysis bandwidth,

$$\eta_{s,r} = \frac{\rho_r c_r S}{\omega M_s} \frac{1}{N_s} \sum_i \sigma_i^{\text{rad}} \quad (32)$$

where $\rho_r c_r$ is the characteristic impedance of the acoustical space, M_s is the mass of the plate, N_s is the mode count for the plate, and σ_i^{rad} is the radiation efficiency for mode i of the plate. Approximations to the summation can be made by grouping the modes into “edge” and “corner” modes.¹⁰

The power transmission coefficients and radiation efficiencies can be calculated with great accuracy. However, the relationship between these parameters and the SEA coupling loss factors requires that some assumptions be made regarding the vibration fields in the connected subsystems. First, the vibrations of the two subsystems are assumed to be uncorrelated. Second, the vibrations of the two subsystems are assumed to be “diffuse”—waves are incident on a point within the subsystem from all angles with equal intensity. Although these assumptions are difficult to prove, even for idealized structures and acoustical spaces, they are generally valid for lightly coupled systems at high frequencies, where many modes participate in the vibration response. The validity of the assumptions for highly coupled subsystems is open to question. Fortunately, the errors incurred using the above equations for highly coupled subsystems are generally small. The assumptions are also open to

question at low frequencies, where only a few modes participate in the response. At these frequencies, the equations above may predict coupling loss factors that are too large. However, it is difficult to quantify the error. In spite of the limited validity of the assumptions, the equations above provide useful estimates of the coupling loss factors, even for highly coupled subsystems at low frequencies.

3.4 Wave versus Modal Approaches

The earliest development of SEA was based on a study of coupled modes. The coupling factor between two coupled modes or oscillators was extended to study the coupling between two subsystems—each with a large number of modes. However, for many types of coupling the proper identification of the subsystem modes is difficult. For example, two plates coupled along one edge may be considered. Use of a clamped boundary condition at the coupling results in modes that allow no displacement at the connection and thus no energy flow. A free boundary condition results in no forces at the connection and again no energy flow. The problem of applying boundary conditions when the coupling between subsystems is at a boundary is difficult to resolve. For this reason, a wave approach is commonly used to compute SEA coupling factors. Following this approach the dynamic response of a subsystem is represented by a series of traveling waves. The wave field is assumed to be diffuse with incoherent waves incident from all directions. The assumption of a diffuse field allows a simple calculation of the SEA coupling factors in terms of wave transmission coefficients. The assumption of a diffuse field can be supported for an ensemble of dynamic systems with modes drawn from a random distribution of resonant frequencies and mode shapes. However, many systems of practical interest do not support this statistical model. For example, a cylindrical structure with periodic stiffeners exhibits strong frequency and wavenumber filtering. The assumption of a diffuse field loses its validity as the vibration propagates along the length of the cylinder. This problem may be alleviated by partitioning the waves (or modes) into different groups according to the direction of propagation. In general, great care must be taken in applying SEA to systems that are not very “random.”

3.5 Damping Loss Factor Theory

The damping loss factors can be predicted analytically for free-layer and constrained-layer treatments. The analysis approach is described in other chapters of this handbook. The damping for an acoustic space is often specified by the average absorption coefficient for the space rather than a damping loss factor. The power dissipated within the acoustical space can be written in terms of the time-average energy and the absorption coefficient as

$$W_a^{\text{diss}} = \omega \frac{S_a}{4k_a V_a} \alpha_{a;\text{diss}} E_a = \omega \eta_{a;\text{diss}} E_a \quad (33)$$

where S_a is the area of the absorbing surface, V_a is the volume of the acoustical space, and k_a is the acoustic wavenumber. It follows that the damping loss factor for an acoustical space can be obtained from the average absorption coefficient by the relation

$$\eta_{a;\text{diss}} = \frac{S_a}{4k_a V_a} \alpha_{a;\text{diss}} \quad (34)$$

where the constant $4V/S$ is commonly referred to as the mean-free path.

3.6 Energy and Response

The SEA power balance equations can be solved to obtain the modal energy or modal power of each subsystem. The final step in the analysis is to relate these variables to the subsystem response. For structural subsystems, the spatial-average mean-square velocity is calculated from the kinetic energy. For resonant vibrations, the time-average kinetic energy is equal to the time-average potential energy. Thus, the average mean-square velocity in a band of frequencies is given by

$$\langle v^2 \rangle_{x,t} = \frac{E}{M} \quad (35)$$

where E is the total energy of all modes in the band and M is the mass of the subsystem. For acoustical subsystems, the spatial-average mean-square sound pressure is calculated from the potential energy,

$$\langle p^2 \rangle_{x,t} = \frac{E}{C_a} \quad (36)$$

where C_a is the compliance of the subsystem, $V/\rho c^2$, for an acoustical space with rigid walls.

The equations above are adequate for large, homogeneous subsystems. However, for small subsystems and for subsystems with significant spatial variations in element stiffness or mass, these equations lose accuracy. When the drive point conductance at the response point is known, either from measurement or from a finite element model, the conversion from energy to response can be carried out with greater accuracy. Since the average conductance is related to the modal density and mass of the system, see Eq. 7, the average mean-square velocity can be written in terms of the modal power as

$$\langle v^2 \rangle_{x,t} = \frac{2}{\pi} \langle G_{\text{pt}}(x, \omega) \rangle_{x, \Delta\omega} \varphi \quad (37)$$

A similar expression can be written for acoustical subsystems

$$\langle p^2 \rangle_{x,t} = \frac{2}{\pi} \langle R_{\text{pt}}(x, \omega) \rangle_{x, \Delta\omega} \varphi \quad (38)$$

where R is the point acoustical resistance. Equations (37) and (38) can also be used to obtain the response at single points within the subsystem rather than spatial averages. This removes a common criticism

of SEA—that the method can only calculate spatial averages of the response.

3.7 Variance

Statistical energy analysis provides a statistical description of the subsystem response. However, in many cases, SEA is used only to obtain an estimate of the mean. Although the mean provides the “best estimate” of the response, this estimate may differ significantly from the response measured for a single member of the ensemble of dynamic systems. The variance or standard deviation of the response provides a measure to quantify the expected confidence intervals for the SEA prediction. When the variance is high, the confidence intervals will be large, and the mean does not provide an accurate estimate of the response.

Using SEA in design requires that a confidence interval be established for the response prediction, so that an upper bound or “worst-case” estimate can be compared with design requirements. If the mean response is used for design, half the products produced will fail to meet the design requirements. Use of the mean plus two or three times the standard deviation (square root of the variance) provides a reasonable upper bound for the response prediction.

Methods to predict the variance of the SEA prediction are not well established, although work is continuing in this area. Often an empirical estimate of the variance or confidence interval is used. In other cases, an estimate based on the modal overlap parameter, the frequency bandwidth of the analysis, and a loading distribution factor is used.^{11,12} The modal overlap parameter, M_{overlap} , is the ratio of the average damping bandwidth for an individual mode to the average spacing between resonance frequencies. This parameter can be written in terms of the damping loss factor and the modal density as

$$M_{\text{overlap}} = \frac{\pi}{2} \omega \eta_d n(\omega) \quad (39)$$

where η_d is the effective total damping loss factor for the subsystem. Large values of the product of the modal overlap parameter and the analysis bandwidth result in low variance and a narrow confidence interval. In this case, the mean is a good estimate of the response. Small values of the product result in high variance and wide confidence intervals. In this case, the mean does not give a good estimate of the response, and the variance should be determined so that an upper bound to the prediction can be obtained.

Failure to include an estimate of the variance in the SEA leads to some misunderstandings regarding the capabilities of SEA. First, SEA is not limited to high frequencies and high modal densities. However, at low frequencies and for low modal densities, the confidence interval for the SEA predictions will be large, so that an estimate of the variance must be made. Second, SEA is not limited to broadband noise analysis. However, for a single-frequency or narrow-band analysis, the confidence interval for the SEA

predictions will be larger than for a one-third octave or octave-band analysis.

4 EXAMPLE

Two examples are presented to illustrate the use of SEA. The first is a simplified model of a ship consisting of a machinery platform, a bulkhead, a deck, and a hull structure, as illustrated in Fig. 7.

This model was originally used to demonstrate the importance of in-plane modes in transmitting vibrational energy. The SEA model consists of seven plates, each with a bending and in-plane subsystem. The in-plane subsystem may be subdivided into in-plane compression and in-plane shear modes. However, these in-plane modes are generally strongly coupled and can be included in a single subsystem. Three line connections are used to connect the plate elements, as shown in Fig. 8.

The first step in the SEA is to set up the coupling matrix for the energy flow equations as shown in Eqs. (22) and (23). The modal densities for each plate are determined using the asymptotic two-dimensional modal density in Table 1. This expression can be used for both the bending and in-plane subsystems by using the correct wavenumber and group speed. The modal density for the in-plane subsystem is determined by summing the modal densities of compressional and shear modes. Each structural connection requires calculation of several coupling factors between the bending and in-plane subsystems of the connected plates. For the upper line connection between the platform and bulkhead plates, five coupling factors are needed: platform bending to bulkhead bending, platform bending to bulkhead in-plane, platform bending to platform in-plane, platform in-plane to bulkhead bending, platform in-plane to bulkhead in-plane, and bulkhead bending to bulkhead in-plane. For each coupling factor a wave approach is used to compute first a power transmission coefficient using Eqs. (28) and (29). The coupling factors are then computed using Eq. (27). The damping factors are computed from the damping loss factors and modal

Figure 7 Simplified ship structure.

Figure 8 SEA ship model.

densities using Eq. (40):

$$\beta_{s;\text{damp}} = \omega \eta_{s;\text{damp}} n_s(\omega) \quad (40)$$

where $\beta_{s;\text{damp}}$ is the damping factor, $\eta_{s;\text{damp}}$ is the damping loss factor, and $n_s(\omega)$ is the modal density of subsystem s . Damping loss factors are often based on empirical estimates or in some cases on measured data. They may also be computed analytically for free-layer and constrained-layer damping treatments. However, the damping loss factor must be calculated for the type of mode being considered. Bending modes often have significantly higher damping than in-plane compression and shear modes. The coupling and damping factors are now assembled to form the coupling matrix for the power balance equations. Each row of this matrix results from power balance for a single subsystem. For row s the diagonal term is the damping factor for subsystem s plus the sum of all coupling factors from subsystem s to other connected subsystems. The off-diagonal terms are the negative values of the coupling factor between subsystem s and the other connected subsystems. The linear matrix equation is then solved to obtain transfer functions between input power and response energy,

$$\text{PTF}_{s;r} = \frac{E_r/n(\omega)_r}{W_s^{\text{in}}} = \frac{\varphi_r}{W_s^{\text{in}}} \quad (41)$$

where $\text{PTF}_{s;r}$ is the transfer function between input power to subsystem s and response modal power for subsystem r .

The second step in the SEA is to relate the modal power to the vibration response. The mean-square velocity is given in terms of the modal power by Eq. (37). The mean-square acceleration in a band of frequencies is simply obtained by dividing the mean-square velocity by the band-center radian frequency squared. For subsystem r the mean-square acceleration is given by

$$\langle a_r^2 \rangle_{x,t} = \frac{2}{\pi} \frac{\varphi_r}{\omega_c^2} \langle G_{r;\text{pt}}(x, \omega) \rangle_{x, \Delta\omega} \quad (42)$$

where ω_c is the band center frequency and $\langle a_r^2 \rangle$ is the mean-squared acceleration response of subsystem r in the band $\Delta\omega$. The average power spectral density in the band is obtained by dividing the mean-square acceleration by the frequency bandwidth. Typically, when calculating the power spectral density (PSD) the bandwidth should be expressed in hertz rather than radians per second.

The third step in the SEA is to compute the power input to the subsystems. In some cases when the input loads are localized and can be represented by point forces, the power input can be determined from force and velocity measurements. Measurement of the power input from applied moments may also be possible but is much more difficult. In other cases when only the applied forces are known, the power input can be determined from the frequency-average conductance at the excitation point, x_s ,

$$W_s^{\text{in}} = \langle F_s^2 \rangle \langle G_{s;\text{pt}}(x_s, \omega) \rangle_{\Delta\omega} \quad (43)$$

The results above can be combined to give a transfer function relating the mean-square response of subsystem ' r ' at point x_r to an applied point force on subsystem ' s ' at point x_s ,

$$\frac{\langle A_r^2 \rangle}{\langle F_s^2 \rangle} = \frac{2}{\pi} \frac{\langle G_{s;\text{pt}}(x_s, \omega) \rangle_{\Delta\omega} \langle G_{r;\text{pt}}(x_r, \omega) \rangle_{\Delta\omega}}{\omega_c^2} \text{PTF}_{s;r} \quad (44)$$

Predictions obtained from this SEA ship model are compared with measured data in Fig. 9. Also shown are an upper limit set at the mean plus two times the predicted SEA standard deviation. The lower plot shows predictions from a typical SEA model in which statistical estimates of the average conductance are used in Eq. (44). The upper plot shows predictions from a hybrid SEA model in which the SEA transfer functions are combined with measured values of

Figure 9 Ship model response.

the conductance. Use of measured conductance data improves the accuracy of the SEA prediction.

The second example is a structural-acoustical model of a automobile. The model is simplified to predict the interior cabin noise from airborne noise sources including the engine, tires, exhaust, and wind noise. The vehicle body is divided into a number of plate and shell elements as shown in Fig. 10. Acoustical elements are added both outside and inside the vehicle. The interior acoustical space is divided into 8 to 27 subspaces with either 2 or 3 sections in the vertical, transverse, and fore-aft directions. A smaller number of subspaces may be used for smaller compact vehicles while a larger number of subspaces would be used for larger sedans, wagons, and SUVs. The exterior acoustical space is also divided into subspaces with a near-field space the same size as the connected body structural element and a far-field space.

The in-plane modes of the body panels do not play a significant role in the sound transmission from the outer acoustical spaces. Thus, for this simplified model a single bending subsystem is used for each panel. The modal density for these bending subsystems is determined from Eq. (14). The modal densities for the acoustical spaces is determined from Eq. (17). Note that in both cases the modal densities are extensive properties so that the modal density of a sum of elements is equal to the sum of the modal densities of the individual elements. Under this condition subdividing the acoustical space does not introduce additional modes to the system. The damping of the acoustical spaces is determined from absorption coefficients for the surfaces within and at the edges of the space. The damping loss factor for the space is determined using Eq. (34) and then used in Eq. (40) to compute the damping factor. The coupling

Figure 10 Vehicle SEA model body elements.

factors between resonant modes of the body panels and the acoustical spaces are computed in terms of the radiation efficiency from Eqs. (32) and (40). The coupling factors between connected acoustic spaces are computed by setting the average transmission coefficient to one in Eq. (31). Finally, coupling factors to account for the sound transmission by mass-law response of the body panels are computed by using the mass-law sound transmission coefficient in Eq. (31).

For this example the power input is determined for the external acoustic spaces from sound pressure level measurements in each space. Transfer functions between the input power to the external near-field acoustic spaces and their acoustic response mean-square sound pressure level are used to determine the required acoustic power input to match the measured acoustic levels.

After solving the SEA power flow equations the mean-square sound pressure level at the operator's ear position is determined from the modal power using Eq. (38). Parameter studies are performed in which the body panel damping loss factor is changed by introduction of damping treatments; the interior absorption coefficient is changed by introducing sound-absorbing headliners and seats; the sound transmission coefficient for the body panels is changed by introducing sound barriers on floor, door, and dash panel structures. Sound transmission through small penetrations in the dash structure and door seals is often shown to be a dominant sound transmission path.

1 INTRODUCTION

There have been great advances in the modeling and analysis of physical phenomena in recent years. These have come in spite of the fact that most physical problems have at least some degree of nonlinearity. Nonlinear effects may take a variety of forms, but they fall into three basic categories. They may be due to (1) geometric and kinematic effects, as with a simple pendulum undergoing large amplitude motion, (2) nonlinear elements (such as a hardening spring or a hydraulic damper), or (3) elements that are piecewise linear (such as bearing with a dead-band clearance region, looseness, and friction). The potential influence of nonlinearities on the overall dynamic behavior of a system depends very strongly on its specific category.

2 NONLINEAR FREE VIBRATION

Simplifying assumptions are often employed to reduce the complexity of nonlinear problems to allow them to be represented by linear expressions that can be solved in a relatively straightforward manner. Such linearization is an almost automatic part of solving many engineering problems. This is due to two basic reasons. First, problems in nonlinear mechanical vibration are considerably more difficult to analyze than their linear counterparts. Second, linearized models capture the essence of many physical problems and offer considerable insight into the dynamic behaviors that are to be expected.

However, this is not always the case. The presence of nonlinear forces in many physical systems results in a considerable number of possible behaviors even for relatively simple models. Mechanisms of instability and sudden changes in response are of fundamental importance in the behavior of nonlinear systems. The closed-form solutions familiar from linear vibration theory are of limited value and give little sense of the complexity and sometimes unpredictability of typical nonlinear behavior.

Solutions to the governing nonlinear equations of motion are obtained using either approximate analytical methods or numerical simulation guided by dynamical systems theory. Due to the inherent complexity of nonlinear vibration, the use of the

geometric, qualitative theory of ordinary differential equations plays a central role in the classification and analysis of such systems.

This chapter is divided into three main sections. The first describes the effects of nonlinear stiffness and damping on free oscillations resulting in multiple equilibria, amplitude-dependent frequencies, basins of attraction, and limit cycle behavior. The second describes the effects of external periodic forcing resulting in nonlinear resonance, hysteresis, subharmonics, superharmonic, and chaos. Low-order, archetypal examples with relevance to mechanical and electrical oscillators are used to illustrate the phenomena. Finally, some more complex examples of systems in which nonlinear effects play an important role are described.

2.1 Autonomous Dynamical Systems

Nonlinear free vibration problems are generally governed by sets of n first-order ordinary differential equations of the form¹

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}) \quad (1)$$

In single-degree-of-freedom oscillators position and velocity are the two state variables. Often the stiffness terms are a function of displacement only and can be derived from a potential energy function. Many mechanical systems have the property that for small displacements this function will be linear in x , and furthermore the damping is often assumed to be governed by a simple, viscous energy dissipation giving linear terms in \dot{x} . In this case, standard vibration theory (see Chapter 12) can be used to obtain exact closed-form solutions giving an exponentially decaying (sinusoidal or monotonic) response.^{2,3} Linear algebra techniques and modal analysis can be used for multi-degree-of-freedom systems. For systems where the induced nonlinearity is small, linearization and certain approximate analytical techniques can be used, but if no restriction is placed on nonlinearity, then numerical methods must generally be used to solve Eq. (1). Some specific examples in the following paragraphs illustrate typical transient behavior.

2.2 The Simple Pendulum

Small-Amplitude Linear Behavior As an introduction to typical nonlinear behavior consider the simple rigid-arm pendulum shown schematically in Fig. 1. It is a simple matter, using Newton's laws or Lagrange's equations,⁶ to derive the governing equation of motion

$$\ddot{\theta} + b\dot{\theta} + (g/L)\sin\theta = 0 \quad (2)$$

where b is the (viscous) damping coefficient. Note that the linear, undamped natural frequency is a constant $\omega_0 = \sqrt{g/L}$. For small angles, $\sin\theta \cong \theta$, and given the two initial conditions, θ_0 and $\dot{\theta}_0$, the pendulum will undergo an oscillatory motion that decays with a constant (damped) period as $t \rightarrow \infty$ coming to rest at $\theta = 0$, the position of static stable equilibrium (Fig. 2a). This equilibrium position acts as a point attractor for all local transients.

It is very useful in nonlinear vibrations to look at phase trajectories in a plot of displacement against velocity. This is shown in Fig. 2b for the pendulum started from rest at $\theta_0 = \pi/8$. The near elliptical nature of these curves (indicating sinusoidal motion) is apparent as the motion evolves in a clockwise direction.

The motion of the pendulum can be thought to be occurring within the potential energy well shown

Figure 1 Schematic diagram of the simple rigid-arm pendulum.

Figure 2 Small-amplitude swings of the damped pendulum illustrating linear motion: (a) times series and (b) phase portrait. ($\theta_0 = \pi/8$, $\omega_0 = 1$, $b = 0.1$.)

in Fig. 3, that is, the integral of the restoring force. The assumption of small angles effectively means that the restoring force is assumed to be linear about the origin (Hooke's law), with a locally parabolic potential energy well. Using the analogy of a ball rolling on this surface, it is easy to visualize the motion shown in Fig. 2.

Large-Amplitude Nonlinear Behavior For large-angle swings of the pendulum the motion is no longer linear. The restoring force induces a softening spring effect. The natural frequency of the system will now be a function of amplitude as the unstable equilibrium at $\theta = \pi$ comes into effect. Linear theory can also be used about an unstable equilibrium, and local trajectories will tend to diverge away from a saddle point. Physically, this is the case of the pendulum balanced upside down. The process of linearization involves the truncation of a power series about the equilibrium positions and characterizes the local motion. Often this information can then be pieced together to obtain a qualitative impression of the complete phase portrait.⁴

Consider the undamped ($b = 0$) pendulum started from rest at $\theta(0) = 0.99\pi$ and shown as a velocity

Figure 3 Underlying potential energy for the pendulum showing the analogy of a rolling ball. The black ball represents stable equilibrium.

time response in Fig. 4a based on direct numerical simulation. These oscillations are far from sinusoidal. The pendulum slows down as it approaches its inverted position, with a natural period of approximately 3.5 times the linear natural period of 2π .

2.3 Duffing's Equation

Another common example of an oscillator with a nonlinear restoring force is an autonomous form of Duffing's equation:

$$\ddot{x} + b\dot{x} + \alpha x + \beta x^3 = 0 \quad (3)$$

which can, for example, be used to study the large-amplitude motion of a pre- or postbuckled beam⁶ or plate, or the moderately large-amplitude motion of the pendulum. The free vibration of a beam loaded axially beyond its elastic critical limit can be modeled by Eq. (4) with negative linear and positive cubic stiffness. In this case the origin (corresponding to the straight configuration) is unstable with two stable equilibrium positions at $x = \pm 2$, for example, when $\alpha = -1$ and $\beta = 4$. Now, not only does the natural period depend on initial conditions but so does the final resting position as the two stable equilibria compete to attract transients. Each equilibrium is surrounded by a domain of attraction. These interlocking domains, or catchment regions, are defined by the separatrix, which originates at the saddle point. It is apparent that some transients will traverse the (double) potential energy well a number of times before sufficient energy has been dissipated and the motion is contained within one well. Clearly, it is difficult to predict which long-term resting position will result given a level of uncertainty in the initial conditions.^{6,7}

2.4 Van der Pol's Oscillator

In the previous section the nonlinearity in the stiffness resulted in behavior dominated by point attractors

Figure 4 Large undamped swings of the undamped pendulum: (a) velocity time series and (b) phase portrait. ($\theta_0 = 0.99\pi$, $\omega_0 = 1$.)

(equilibria). Periodic attractors (limit cycles) are also possible in autonomous dynamical systems with nonlinear damping. A classical example relevant to electric circuit theory is Van der Pol's equation^{1,8}

$$\ddot{x} - h(1 - x^2)\dot{x} + x = 0 \quad (4)$$

where h is a constant. Here, the damping term is positive for $x^2 > 1$ and negative for $x^2 < 1$, for a positive h . When h is negative, local transient behavior simply decays to the origin rather like in Fig. 2. However, for positive h , a stable limit cycle behavior occurs where the origin is now unstable and solutions are attracted to a finite-amplitude steady-state oscillation. This is shown in Fig. 5, for $h = 1$ and $x_0 = \dot{x}_0 = 0.1$, as a time series in Fig. 5a and a phase portrait in Fig. 5b. Initial conditions on the

Figure 5 Stable limit cycle behavior exhibited by Van der Pol's equation: (a) time series and (b) phase portrait. ($x_0 = 0.1, \dot{x}_0 = 0.1, h = 1.0$.)

outside of this limit cycle would be similarly attracted. This phenomenon is also known as a self-excited or relaxation oscillation.^{8,9} Related physical examples include mechanical chatter due to dry friction effects between a mass and a moving belt (stick-slip),¹⁰ and certain flow-induced aeroelastic problems including galloping and flutter.¹¹

2.5 Instability

Nonlinear free vibration problems are generally dominated by the influence of equilibria on transient behavior. There are several definitions of stability, but generally if a small perturbation causes the system to move away from equilibrium, then this is a locally unstable state. This is familiar from linear vibration theory where transient behavior is described by the characteristic eigenvalues of the system. For example, the linear oscillator in Fig. 2 has two complex conjugate characteristic eigenvalues with negative real parts. A linearization about the inverted position for the pendulum would lead to one positive real eigenvalue resulting in divergence. Similarly, behavior in the vicinity of equilibrium for the Van der Pol oscillator ($h > 0$) is characterized by complex conjugate eigenvalues but with positive real parts and hence a growth of unstable oscillations. The amplitude of the oscillation in this case is limited by nonlinear effects.

Such systems tend to be sensitive to certain control parameters, for example, h in Eq. (5). More generally a system of the form

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \boldsymbol{\mu}) \quad (5)$$

must be considered where the external parameters $\boldsymbol{\mu}$ allow a very slow (quasi-static) evolution of the dynamics. In nonlinear dynamic systems such changes in these parameters may typically result in a qualitative change (bifurcation) in behavior, and for systems under the operation of one control parameter these instabilities take place in one of two well-defined, generic ways. Both of these instability mechanisms have been encountered in the previous sections. The loss of stiffness is associated with the passage of an eigenvalue into the positive half of the complex plane, as shown in Fig. 6. This stability transition is known

Figure 6 Two generic instabilities of equilibria under the operation of a single control.

as the saddle node but is also referred to as a fold bifurcation and is encountered, for example, in limit-point snap-through buckling in structural mechanics.⁶ The loss of damping is associated with the passage of a pair of complex conjugate eigenvalues into the positive half of the complex plane. This instability mechanism is known as a Hopf bifurcation.^{12,13}

It is also possible for the nonlinearity to determine stability of motion in the neighborhood of an equilibrium point. In such situations, a nonlinear analysis must be employed. For example, consider the dynamic system represented by the differential equations:

$$\begin{aligned}\dot{x} &= x^2 y - x^5 \\ \dot{y} &= -y + x^2\end{aligned}$$

One equilibrium point is (0,0). The linearized equations about this point are

$$\begin{aligned}\dot{x} &= 0 \\ \dot{y} &= -y\end{aligned}$$

and the eigenvalues are 0, and -1 . Since one of the eigenvalues has a zero real part [the (0,0) equilibrium point is not hyperbolic], one cannot draw any conclusions with regard to the stability of the equilibrium point from the eigenvalues of the linearized system. In order to properly analyze this system, one can employ center manifold theory,^{30,32} which states that the flow in the center manifold determines the stability of a dynamic system operating in the neighborhood of a nonhyperbolic equilibrium point. A detailed analysis shows that the dynamics behavior of this example system operating on the center manifold is

$$\dot{z} = z^4 + \text{higher-order terms} \quad (6)$$

Examination of this equations shows that this system will be unstable in the neighborhood of $z = 0$, which then indicates that the original system is unstable in the neighborhood of the (0,0) equilibrium point.

3 NONLINEAR FORCED VIBRATION

3.1 Nonautonomous Dynamical Systems

When a dynamic system is subjected to external excitation a mathematical model of the form

$$\ddot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, t) \quad (7)$$

results. This system can be made equivalent to Eq. (1) by including the dummy equation $\dot{t} = 1$ to give an extra phase coordinate. In forced nonlinear vibration primary interest is focused on the case where the input (generally force) is assumed to be a periodic function. For a single-degree-of-freedom oscillator the forcing phase effectively becomes the third state variable. If the system is linear, then the solution to Eq. (7) will

consist of a superposition of a complementary function that governs the transient free-decay response, and a particular integral that governs the steady-state forced response (see Chapter 12). The steady-state oscillation generally responds with the same frequency as the forcing and acts as a periodic attractor to local transient behavior.

If Eq. (7) is nonlinear, then it is generally not possible to obtain an exact analytical solution. A number of choices are available: (1) linearize about the static equilibria and obtain solutions that are valid only in a local sense, (2) use an approximate analytical method and assume relatively small deviation from linearity, for example, use a perturbation scheme,¹⁴ and (3) simulate the equation of motion using numerical integration.¹⁵ The first of these approaches leads to the familiar resonance results from standard vibration theory (see Chapter 12). A large body of research has been devoted to the second approach.^{1,14,16,17} However, due to recent advances in, and the availability of, digital computers and sophisticated graphics, the third approach has achieved widespread popularity in the study of nonlinear vibrations. Furthermore the numerical approach has been enhanced by the development of the qualitative insight of dynamical systems theory.¹⁸

3.2 Nonlinear Resonance

The steady-state response of nonlinear vibration problems modeled by Eq. (7) with external forcing of the form

$$G \sin(\omega t + \phi) \quad (8)$$

exhibit some interesting differences from their linear counterparts. Consider the harmonically forced Duffing equation, that is, Eq. (8) added to the right-hand side of Eq. (4). For sufficiently large G the cubic nonlinearity is induced, and a typical resonance amplitude response is plotted as a function of forcing frequency in Fig. 7 for $G = 0.1$ and three different damping levels. These curves were obtained using the method of harmonic balance^{1,7} and illustrate several nonlinear features. For relatively small amplitudes, that is, in a system with relatively small external forcing, or

Figure 7 Nonlinear resonance illustrating the jump in amplitude. This steady-state motion occurs about the offset static equilibrium position. ($b = 0.18, 0.25, 0.35$, $\alpha = -1$, $\beta = 1$, $G = 0.1$.)

heavy damping, and generally away from resonance, the response is not significantly different from the linear case. However, for larger amplitudes the softening spring effect causes a bending over of the curves. This is related to the lengthening effect of amplitude on the natural period of the underlying autonomous system and causes the maximum amplitude to occur somewhat below the natural frequency, and for some frequencies multiple solutions are possible. For example, for the case $b = 0.18$, there are three steady-state solutions near $\omega = 0.8$. Two are stable and they are separated by an unstable solution (not shown). The two stable steady-state cycles are periodic attractors and compete for the capture of transient trajectories, that is, in this region different initial conditions lead to different persistent behavior. The jump phenomenon is observed by gradually (quasi-statically) changing the forcing frequency ω while keeping all the other parameters fixed. Starting from small ω and slowly increasing, the response will suddenly exhibit a finite jump in amplitude and follow the upper path. Now starting with a large ω and gradually reducing, the response will again reach a critical state resulting in a sudden jump down to the small-amplitude solution. These jumps occur at the points of vertical tangency and bound a region of hysteresis.

A hardening spring exhibits similar features except the resonance curves bend to the right. A physical example of this type of behavior can be found in the large-amplitude lateral oscillations of a thin elastic beam or plate. In this case the induced in-plane (stretching) force produces a hardening (cubic) nonlinearity in the equations of motion, that is, α and β both positive, and for certain forcing frequencies the beam can be perturbed from one type of motion to another. The domains of attraction often consist of interlocking spirals, and hence it may be difficult to determine which solution will persist given initial conditions to a finite degree of accuracy in a similar manner to the unforced case.

3.3 Subharmonic Behavior

Periodic solutions to ordinary differential equations need not necessarily have the same period as the forcing term. It is possible for a system to exhibit subharmonic behavior, that is, the response has a period of n times the forcing period. Subharmonic motion can also be analyzed using approximate analytical techniques.^{1,14,16}

Figure 8 illustrates a typical subharmonic of order 2 obtained by numerically integrating Duffing's equation:

$$\ddot{x} + b\dot{x} + \alpha x + \beta x^3 = G \sin \omega t \quad (9)$$

for $b = 0.3$, $\alpha = -1$, $\beta = 1$, $\omega = 1.2$, and $G = 0.65$. Subharmonic behavior is generally a nonlinear feature and is often observed when the forcing frequency is close to an integer multiple of the natural frequency. Also, subharmonics may result due to a bifurcation from a harmonic response and thus may complicate the

Figure 8 Subharmonic oscillations in Duffing's equation: (a) time series and (b) phase projection. ($b = 0.3$, $\alpha = -1$, $\beta = 1$, $\omega = 1.2$, $G = 0.65$.)

approximate scenario shown in Fig. 7. Superharmonics corresponding to a response that repeats itself a number of times within each forcing cycle are also possible especially at low excitation frequencies.

3.4 Poincaré Sampling

A useful qualitative tool in the analysis of periodically forced nonlinear systems is the Poincaré section.⁴ This technique consists of stroboscopically sampling the trajectory every forcing cycle or at a defined surface of section in the phase space. The accumulation of points will then reflect the periodic nature of the response. A fundamental harmonic response appears as a single point simply repeating itself. The location of this point on the phase trajectory and hence in the (x, \dot{x}) projection depends on the initial conditions. For example, consider the subharmonic response of Fig. 8. The forcing period is $T = 2\pi/\omega = 5.236$, and if the response is inspected whenever t is a multiple of T , then 2 points are visited alternately by the trajectory as shown by the dots in Fig. 8b. The Poincaré sampling describes a mapping and can

also be used to study the behavior of transients and hence stability. Further refinements to this technique have been developed including the reconstruction of attractors using time-delay sampling.⁴ This is especially useful in experimental situations where there may be a lack of information about certain state variables, or in autonomous systems where there is no obvious sampling period.

3.5 Quasi-periodicity

Another possible response in forced nonlinear vibration problems is the appearance of quasi-periodic behavior. Although the superposition of harmonics, including the beating effect, is commonly encountered in coupled linear oscillations, it is possible for nonlinear single-degree-of-freedom systems to exhibit a relatively complicated response where two or more incommensurate frequencies are present. For a two-frequency response local transients are attracted to the surface of a toroidal phase space, and hence Poincaré sampling leads to a continuous closed orbit in the projection because the motion never quite repeats itself. Although a quasi-periodic time series may look complicated, it is predictable. The fast Fourier transform (FFT) is a useful technique for identifying the frequency content of a signal and hence distinguishing quasi-periodicity from chaos.

3.6 Piecewise Linear Systems

There are many examples in mechanical engineering where the stiffness of the system changes abruptly, for example, where a material or component acts differently in tension and compression, or a ball bouncing on a surface. Although they are linear within certain regimes, the stiffness is dependent on position and their behavior is often strongly nonlinear. If such systems are subjected to external excitation, then a complex variety of responses are possible.^{19,20} Related problems include the backlash phenomenon in gear mechanisms where a region of

free play exists.⁶ Nonlinearity also plays a role in some Coulomb friction problems including stick-slip where the discontinuity is in the relative velocity between two dry surfaces.¹ Feedback control systems often include this type of nonlinearity.²¹

3.7 Chaotic Oscillations

The possibility of relatively simple nonlinear systems exhibiting extremely complicated (unpredictable) dynamics was known to Poincaré about 100 years ago and must have been observed in a number of early experiments on nonlinear systems. However, the relatively recent ability to simulate highly nonlinear dynamical systems numerically has led to a number of interesting new discoveries with implications for a wide variety of applications, especially chaos, that is, a fully deterministic system that exhibits randomlike behavior and an extreme sensitivity to initial conditions. This has profound implications for the concept of predictability and has stimulated intensive research.²²

Figure 9 shows a chaotic time series obtained by the numerical integration of Eq. (9) for appropriately selected b , α , β , G , and ω using a fourth-order Runge–Kutta scheme.¹⁴ Here, transient motion is allowed to decay leaving the randomlike waveform shown [Fig. 9a]. This response, which traverses both static equilibria ($x_e = \pm 1$), may be considered to have an infinite period. An important feature of chaos, in marked contrast to linear vibration, is a sensitive dependence on initial conditions, and this figure also shows (dashed line) how initially adjacent chaotic trajectories diverge (exponentially on the average) with time. Given a very small difference in the initial conditions, that is, a perturbation of 0.001 in x at time $t = 750$, the mixing nature of the underlying (chaotic) attractor leads to a large difference in the response. Figure 9b shows the data for the original time series as a phase projection. Although the response remains bounded, the loss of predictability for increasing time is apparent.

Figure 9 Chaotic response of Duffing's equation including exponential divergence of initially close trajectories; parameters same as Fig. 8, $G = 0.5$. (a) Time series, the initial separation in x is 0.001 at time $t = 750$, and (b) phase projection.

However, unlike truly random systems, the randomness of a chaotic signal is not caused by external influences but is rather an inherent dynamic (deterministic) characteristic. Poincaré sampling can be used effectively to illustrate the underlying structure of a chaotic response. A number of experimental investigations of chaos have been made in a nonlinear vibrations context including the buckled beam,⁶ although early work on nonlinear circuits made a significant contribution.⁷ Consider the example of a physical analog of the twin-well potential system described by Eq. (9), that is, a small cart rolling on a curved surface.²³ A chaotic attractor based on experimental data is shown in Fig. 10 where 10,000 Poincaré points, that is, forcing cycles, are plotted in the phase projection. A similar pattern is obtained by taking a Poincaré section on

Figure 10 Poincaré section of the chaotic attractor exhibited by an experimental (mechanical) analog²³ of Eq. (9).

the data of Fig. 9. The evolution of the trajectory follows a stretching and folding pattern, exhibiting certain fractal characteristics⁶ including a noninteger dimension and can be shown to give a remarkably close correlation with numerical simulation.²³

For certain parameter ranges catchment regions in forced oscillations also have fractal boundaries, that is, self-similarity at different length scales, although these can occur for periodic attractors. An example is given in Fig. 11 based on numerical integration of Eq. (9) with $b = 0.168$, $\alpha = -0.5$, $\beta = 0.5$, $G = 0.15$, and $\omega = 1$. Here a fine grid of initial conditions is used to determine the basins of attraction for two periodic oscillations, one located within each well. Investigation of all initial conditions is a daunting task, especially for a higher-order system, but certain efficient techniques have been developed.²⁴ A relatively rare analytical success used to predict the onset of fractal basin boundaries based on homoclinic tangencies is Melnikov theory.¹⁸

A further remarkable feature of many nonlinear systems is that they follow a classic, universal route to chaos. Successive period-doubling bifurcations can occur as a system parameter is changed, and these occur at a constant geometric rate, often referred to as Feigenbaum's ratio. This property is exhibited by a large variety of systems including simple difference equations and maps.^{4,13,18} Other identified routes to chaos include quasi-periodicity, intermittency and crises, and chaotic transients and homoclinic orbits.¹³

Two major prerequisites for chaos are (1) the system must be nonlinear and (2) the system must have at least a three-dimensional phase space. A number of diagnostic numerical tools have been developed to characterize chaotic behavior, other than the Poincaré map. The randomlike nature of a chaotic

Figure 11 Fractal basin boundary for Duffing's equation based on numerical simulation ($b = 0.168$, $\alpha = -0.5$, $\beta = 0.5$, $\omega = 1$, $G = 0.15$). The black (white) regions represent initial conditions that generate a transient leading to the periodic attractor in the right (left) hand well.

signal is reflected in a broadband power spectrum with all frequencies participating.²⁵ The widespread availability of fast Fourier transform software makes power spectral techniques especially attractive in an experimental situation. Also, the divergence of adjacent trajectories can be measured in terms of Lyapunov exponents.²⁶ The autocorrelation function also has been used to illustrate the increasing loss of correlation with time lag. Various measures of dimension have been developed as well to establish the relation between fractals, chaos, and dynamical behavior.

3.8 Instability

Analogous to the instability of (static) equilibria under the operation of one control parameter, periodic (dynamic) cycles also lose their stability in a small number of generic ways. Figure 12 summarizes the typical stability transitions encountered in nonlinear forced vibration problems. Here, Poincaré sampling is used to obtain information on local transient behavior in terms of characteristic multipliers that describe the rate of decay of transients onto a periodic attractor, and hence, in the complex plane characterizes the stability properties of a cycle. This is familiar as the root locus in control theory based on the z transform.²¹ Slowly changing a system parameter may cause penetration of the unit circle and hence the local growth of perturbations. The cyclic fold is the underlying mechanism behind the resonant amplitude jump phenomenon, and the flip bifurcation leads to subharmonic motion and may initiate the period-doubling sequence.

The Neimark bifurcation is much less commonly encountered in mechanical vibration. Also, other types of instability are possible for nongeneric systems, for example, a perfectly symmetric, periodically forced pendulum may exhibit a symmetry-breaking pitchfork bifurcation.¹⁸

Again these instability phenomena can also be analyzed using approximate analytical techniques. Small perturbations about a steady-state solution are used to obtain a variational (Mathieu-type) equation, the stability of which can then be determined using Floquet theory or the Routh–Hurwitz criteria.^{1,14,16}

3.9 Nonlinear Normal Modes

The technique of nonlinear normal modes (NNM) can be thought of as an extension of classical linear modal methods. Unlike linear systems, there may be more nonlinear modes than there are degrees of freedom for a given system. For example, bifurcations may occur that produce modes not predicted by a linearized analysis. Also, the principle of superposition does not, in general, apply to NNM as it does to linear modes.

This technique has been successfully used to analyze a number of complex problems, including nonlinear resonances and localization phenomena associated with the vibration of rotating bladed disk assemblies and nonlinear isolation systems. For situations where the nonlinearities have a strong influence on the system response, NNM can be a very powerful analysis tool. It can be used as a model reduction technique, allowing for the development of approximate models that neglect effects that do not substantially influence the phenomena being analyzed. Vakakis et al.³¹ provide a comprehensive discussion of nonlinear normal modes.³⁰

4 EXAMPLES IN PRACTICE

The preceding discussion has been aimed at acquainting the reader with the basic phenomena that may occur in nonlinear dynamical systems and with the basic tools that are used to analyze such systems. The reader must first ask the basic question: Are the nonlinearities an important component in the dynamical behavior of my system? That is, can the system behavior be adequately explained with a linear model? This question can be answered by posing the following questions:

- Is there more than one equilibrium point in the system?
- Do any of the eigenvalues of the linearized system about the equilibrium points have zero real parts?
- Does a frequency analysis of the steady-state vibration response show significant components at frequencies other than those that are driving the system? This may include sub- and superharmonics of the driving frequency.

Figure 12 Generic instabilities of cycles under the operation of a single control.

If the answer to any of these questions is “yes,” then a nonlinear analysis is required. The nonlinearities are significant and must be considered in the dynamical analysis. The following paragraphs provide some examples of nonlinear systems and discuss the significance of the nonlinear terms with regard to the overall dynamics.

4.1 Example 1: Rotor with Rubbing

Instability Driven by Nonlinear Effects Rubbing is common in rotating mechanical systems. There has been considerable debate over the years as to the true significance of rubbing as a destabilizing phenomena. Certainly, there is no doubt that many rotor systems experience rubbing regularly with no detrimental effects. On the other hand, there are numerous documented cases of high-amplitude rotor whirl driven by friction-induced contact resulting from rubbing. Childs²⁹ gives a good discussion of this topic for most rotor systems. For such systems, the stability may depend upon the amplitude of the disturbance away from the nominal “zero” location.

In order to gain some basic insight, consider a simple Jeffcott-type rotor model interacting across a

clearance, δ , with a stationary housing, as shown in Fig. 13.

$$m\ddot{x} + c\dot{x} + kx + F_T \cos(\phi) - F_N \sin(\phi) = 0$$

$$m\ddot{y} + c\dot{y} + ky + F_N \cos(\phi) - F_T \sin(\phi) = 0$$

$$F_N = k_c(R - \delta)\Psi$$

$$F_T = \mu F_N \text{sign}(v_c)$$

$$\Psi = 1 \quad \text{if } R - \delta > 0$$

$$\Psi = 0 \quad \text{if } R - \delta < 0$$

where μ is the friction coefficient between the rotor and the housing, k_c is the contact stiffness, v_c is the relative velocity at the contact point, F_N and F_T are the normal and tangential forces at the contact point, and ϕ is the contact angle.

Two response cases are shown in Fig. 14. If the initial condition is sufficiently small such that the rotor does not contact the housing, then the vibration simply dies out to a zero steady-state level (Fig. 14a). However, for a certain running speed range and sufficiently large initial condition, the rotor will whirl in a limit cycle, as shown in Fig. 14b.

4.2 Example 2: Systems with Clearance and Looseness

Superharmonic Vibrations and Chaos Looseness-type nonlinearities are common in mechanical systems. In fact, a certain amount of clearance is generally required between mechanical components if they are to be mated together and later separated. Often, this requirement is mitigated by employing press-fits and shrink-fits to mate and unmate the components. However, loosening and clearances may still appear as a result of temperature effects, centrifugal forces, wear, and the like. On Occasion, clearance is a fundamental design aspect. For example, impact and friction dampers require looseness in order to function.

One common indicator of the presence of such effects is the presence of significant frequency components at integer multiples of the running speed during steady-state operation. It should be noted that the presence of radial nonsymmetry due to support stiffness, rotating inertia, and so forth tends to exacerbate the influence of nonlinearities. Chaotic behavior has even been observed in such systems.

From a practical perspective, vibration signals are often analyzed for the purpose of monitoring the health of a structure or machine. There are a number of approaches, but they all basically compare the vibration signatures of the subject structure to that of a healthy structure of the same type. Often, deterioration is associated with effects that have a nonlinear influence on dynamic behavior, with small changes producing an amplified effect that is more readily discernible than would be the case if the influence was linear in nature. For example, the presence of a crack introduces a nonlinear feature as the crack

Figure 13 Diagram of rotor with a clearance: (a) frontal view and (b) side view.

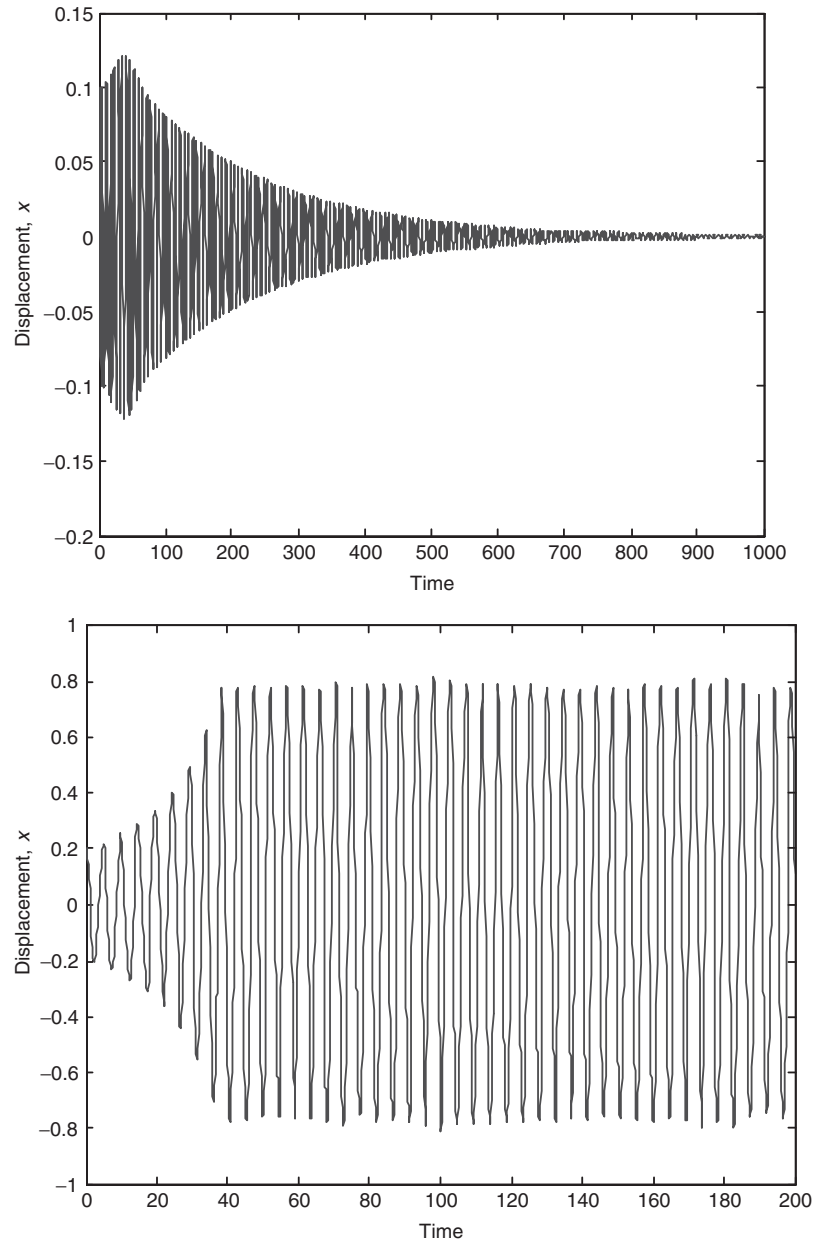

Figure 14 Rotor response of two different initial conditions: (a) low-amplitude initial condition (no casing contact) and (b) higher amplitude initial condition (casing is contacted).

opens and closes. Also, bearing and joint wear results in increased clearances and looseness. So, identifying and quantifying such effects and their influence on vibration characteristics has widely shown to be a useful tool for health and condition monitoring.^{28,29}

A practical example of such systems is the sound pressure levels produced by a fan with different levels

of imbalance. The noise was measured after different magnitude masses (4.636, 7.043, 16.322, and 32.089 g) were placed on one blade of the centrifugal fan in the unit. The microphone position used was 36 inches from the front of the unit (the same side of the unit as the door to the anechoic room) and centered at the front of the air-conditioning unit. Figure 15

Figure 15 Narrow-band sound pressure level measured at 0.9 m from a fan with various imbalance masses added to the blower wheel (400-Hz frequency range).³⁴

shows the narrow-band results for the cabinet sound pressure levels. The frequency range for these measurements was chosen to be in the low-frequency range of 0 to 400 Hz. This is because the added masses mainly cause low-frequency force excitation. Note that the masses create pure tone noise at the fundamental rpm/60 of the wheel and multiples (i.e., about 18.5 Hz and integer multiples). These pure tones become more and more pronounced as the out-of-balance mass is increased. They occur because of nonlinearities in the air-conditioning system caused by structural looseness and rattling. This phenomenon causes distortion of the sine wave shape of the fundamental pure tone out-of-balance force. This distortion effect causes harmonic multiples of the force to be created. There is an increase in noise of almost 10 dB when the largest out-of-balance mass is attached to the wheel. This increased noise (which is mainly low frequency as might be expected) was very evident to people present near the unit being tested. This low-frequency out-of-balance noise is quite unpleasant subjectively for people since it can be felt also as vibration by the human body.

5 SUMMARY

The field of nonlinear vibration has made substantial progress in the last two decades, developing tools and techniques for the analysis of complex systems. These years have seen the development and maturation of such areas as chaos and bifurcation analysis. However, substantial progress in a number of areas is still needed. For example, the analysis of high-order, nonlinear dynamical systems is still a difficult proposition.

The preceding discussion is meant to provide an overview of the field, including vibration phenomena that is uniquely nonlinear (such as limit cycles and

chaos) and analysis techniques that can be used to study such systems. References are provided to allow for more detailed information on specialized topics.

HUMAN HEARING AND SPEECH

CHAPTER 19

GENERAL INTRODUCTION TO HUMAN HEARING AND SPEECH

Karl T. Kalveram
Institute of Experimental Psychology
University of Duesseldorf
Duesseldorf, Germany

1 INTRODUCTION

This chapter discusses the way we hear, how sounds impair behavior, and how noise or hearing loss affect speech communication. Sound waves reaching the outer ear are physically characterized by frequency, intensity, and spectrum. As physiological acoustics points out, these physical variables are coded by hair cells in the inner ear into nerve impulses that our brains interpret as pitch, loudness, and timbre. Psychoacoustics deals with the quantitative relationship between the physical properties of sounds and their psychological counterparts. Noisiness and annoyance caused by sounds can also be subsumed to psychoacoustics, although they strongly depend also on the nonauditory context of the sounds. Speech recognition mirrors a particular aspect of auditory processing. Here, the continuous sonic stream is first partitioned into discrete sounds: vowels and consonants. These *phonemes* are then compiled to words, and the words to sentences, and so on. Therefore, speech recognition is hampered by background noise, which masks frequency bands relevant for phoneme identification, by damage to hair cells through intense noise or aging, which code for these relevant frequency bands, and by distortion or absence of signals necessary to delimit chunks on different levels of speech processing.

2 PHYSIOLOGICAL ACOUSTICS

Physiological acoustics tells us that the sound is converted by the eardrum into vibrations after passing through the outer ear canal. The vibrations are then transmitted through three little bones in the middle ear (hammer, anvil, and stirrup) into the cochlea in the inner ear (see Fig. 1, right side) via the oval window. In the fluid of the cochlea the basilar membrane is embedded, which when uncoiled resembles a narrow trapezoid with a length of about 3.5 cm, with the small edge pointing at the oval window. The incoming vibrations cause waves to travel along the basilar membrane. Sensors called inner hair cells and outer hair cells, which line the basilar membrane, transmute the vibrations into nerve impulses according to the bending of the hair cell's cilia.^{1,2} **Place theory** links the pitch we hear with the place on the basilar membrane where the traveling waves achieve a maximal displacement. A pure tone generates one maximum, and a complex sound generates several maxima according to its spectral components. The closer the group of the maxima is placed to the

oval window, the higher the pitch, whereas the configuration of the maxima determines the timbre. The loudness of a sound seems to be read by the brain according to the number of activated hair cells, regardless of their location on the basilar membrane. While the inner hair cells primarily provide the afferent input into the acoustic nerve, the outer hair cells also receive efferent stimulation from the acoustic nerve, which generates additional vibrations of the basilar membrane, and leads to otoacoustic emissions. (See Fig. 18 of Chapter 20. Do not confuse with tinnitus.) These vibrations seem to modulate and regulate the sensitivity and gain of the inner hair cells. **Temporal theory** assumes that the impulse rate in the auditory nerve correlates to frequency, and therefore, also contributes to pitch perception (for details, see Chapter 20).

The ear's delicate structure makes it vulnerable to damage. **Conductive hearing loss** occurs if the mechanical system that conducts the sound waves to the cochlea loses flexibility, for instance, through inflammation of the middle ear. **Sensorineural hearing loss** is due to a malfunctioning of the inner ear. For instance, prolonged or repeated exposure to tones and/or sounds of high intensity can temporarily or even permanently harm the hair cell receptors (see Table 2 of Chapter 21 for damage risk criteria). Also, when people grow older, they often suffer a degeneration of the hair cells, especially of those near to the oval window, which leads to a hearing loss especially regarding sound components of higher frequencies.

3 PSYCHOLOGICAL ACOUSTICS

Psychological acoustics is concerned with the physical description of sound stimuli and our corresponding perceptions. Traditional psychoacoustics and *ecological psychoacoustics* deal with different aspects in this field.

Traditional psychoacoustics can further be subdivided into two approaches: (1) The **technical approach** concerns basic capabilities of the auditory system, such as the *absolute threshold*, the *difference threshold*, and the *point of subjective equality* with respect to different sounds. The psychological attributes, for instance, pitch, loudness, noisiness, and annoyance, which this approach refers to, are assumed to be quantifiable by so-called technical indices. These are values derived from physical measurements, for instance, from frequency, sound pressure, and duration

Figure 1 Speaking and hearing. (Left side) Vocal tract, generating “supercalifragilisticexpialidocious.” (Middle part) Corresponding sound pressure curve and the sonogram of the first three syllables. (Right side) Ear, receiving the sonic stream and converting it to nerve impulses that transmit information about frequency, intensity, and spectrum via the auditory nerve to the brain, which then extracts the meaning. The figure suggests that production and perception of speech sounds are closely adapted to each other.

of sounds, which are then taken as the reaction of an average person. The special scaling of these measurements is extracted from the exploration of a number of normally sensing and feeling subjects. (2) The **psychological approach** uses such indices as the metric base but relates them with explicit measurements of the corresponding psychological attributes. This requires a specification of these attributes by appropriate psychological measurement procedures like *rating* or *magnitude scaling*.² The psychological approach principally provides, besides of the mean, also the scattering (standard deviation) among the individual data.

The **absolute threshold** denotes the minimum physical stimulation necessary to detect the attribute under consideration. A sound stimulus S described by its (physical) intensity I is commonly expressed by the **sound pressure level** $L = 20 \log p/p_0 = 10 \log I/I_0$, see Eq. (36) in Chapter 2. Thereby, I_0 refers to the intensity of the softest pure tone one can hear, while p and p_0 refer to the sound pressure. Conveniently, $p_0 = 20 \mu\text{Pa}$, and p can be measured by a calibrated microphone. Although L is a dimensionless number, it is given the unit **decibel (dB)**. Methodically, the absolute hearing threshold is defined as that sound pressure level of a pure tone that causes a detection with a probability of 50%. The thresholds are frequency dependent, whereby the minimal threshold resides between 1 and 5 kHz. This is that frequency domain that is most important for speech. As can be seen in Fig. 1 of Chapter 20, at the left and the right of the minimal value, the hearing

thresholds continuously increase, leaving a range of approximately 20 to 20,000 Hz for auditory perception in normal hearing persons. A person’s **hearing loss** can be quantified through determination of the frequency range and the amount by which the absolute hearing thresholds in this range are elevated. The top of Figure 1 of Chapter 20 indicates the saturation level, where an increase of intensity has no effect on perceived loudness. This level, which is located at about 130 dB, is experienced as very uncomfortable or even painful. **Masking** labels a phenomenon by which the absolute threshold of a tone is raised if a sound more or less close in frequency, called the masker, is added. Thus, an otherwise clearly audible tone can be made inaudible by another sound. *Simultaneous masking* refers to sounds that occur in synchrony, and *temporal masking* to sounds occurring in succession. Thereby, *forward masking* means that a (weak) sound following the masker is suppressed, whereas in *backward masking*, a (weak) sound followed by the masker is suppressed. To avoid beats in an experimental setup, the masker is often realized as narrow-band noise. Tones that are higher in frequency than the center frequency of the masker are considerably more strongly suppressed than those below the center frequency. Enhancing the masker’s intensity even broadens this asymmetry toward the tones whose frequency exceeds the center frequency. Simultaneous and temporal masking allow to sparsely recode sound signals without a recognizable loss of quality—as performed, for instance, in the **audio compression format MP3** for music. Here, a computer algorithm quickly calculates those parts of the audio input that will be inaudible and cancels them

in the audio signal to be put out. Also broadband noise and pink noise added to the auditory input can impair sound recognition by masking. This is of importance especially in speech perception.

The **difference threshold**, also called the **just noticeable difference (JND)**, describes the minimum intensity ΔI by which a variable test stimulus S (comparison stimulus) must deviate from a standard stimulus S_0 (reference stimulus) to be recognized as different from S_0 . Both stimuli are usually presented as pairs, either simultaneously if applicable, or sequentially. ΔI is, like the absolute threshold, statistically defined as that intensity difference by which a deviation between both stimuli is recognized with a probability of 50%. Regarding pure tones of identical frequency, the difference thresholds roughly follow **Weber's law**, $\Delta I/I_0 = k = \text{const.}$, where I_0 refers to intensity of S_0 , and k approximates 0.1. **Fechner's law**, $E = \text{const} \log I/I_0$, is assumed to hold for all kinds of sensory stimulation fulfilling Weber's law.² Here, E means the strength of the experienced loudness induced by a tone of intensity I , and I_0 the absolute threshold of that tone. Both diminishing and enhancing loudness by 3 dB roughly correspond to the JND. Fechner's law is the starting point of a **loudness scale** that is applicable to sounds with arbitrary, but temporally uniform, distributions of spectral intensity. To account for the frequency-dependent sensitivity of the human ear, the sound pressure measurements pass an appropriate filter. Mostly, a filter is chosen whose characteristic is inversely related to the 40-phon contour sketched in Fig. 2 of Chapter 21 (40 phon—for definition see below—characterizes a clearly audible, but very soft sound). We call this the **A-weighted sound pressure level**. It provides a technical loudness index with the unit dB.

The **point of subjective equality (PSE)** refers to cases where two physically different stimuli appear as equal with respect to a distinct psychological attribute, here the experienced loudness. Considered statistically, the PSE is reached at that intensity, where the test stimulus is judged louder than the standard with a probability of 50%. The concept allows to construct an alternative **loudness scale with the unit phon**, the purpose of which is to relate the loudness of tones with diverse frequencies and sound pressure levels to the loudness of 1-kHz tones. The scaling procedure takes a pure tone of 1 kHz at variable sound pressure levels as standards. Test stimuli are pure tones, or narrow-band noise with a clear tonal center, which are presented at different frequencies. The subject's task is to adjust the intensity of the test stimulus such that it appears as equally loud compared to a selected standard. Figure 2 of Chapter 21 shows the roughly U-shaped dependency of these sound pressure levels on frequency. All sounds fitting an equal-loudness contour are given the same value as the standard to which they refer. However, the unit of this scale is renamed from dB into phon. In other words, all sounds relabeled to x phon appear as equally loud as a pure tone of 1 kHz at a sound pressure level of x dB.

The **quantitative specification of a psychological attribute** requires one to assume that the subjects assign scaleable perceived strengths E to the physical stimuli S to which they are exposed. In rating, typically a place between two boundaries that represent the minimal and the maximal strength has to be marked. The boundaries are given specific numbers, for instance, 0 and 100, and the marked place is then converted into a corresponding number assumed to mirror E . In **magnitude scaling**, typically a physical standard S_0 is additionally provided that induces the perceptual strength E_0 to be taken as the internal standard respective unit. Then, the subject is given a number $0 < x < \infty$ and instructed to point at that stimulus S , which makes the corresponding perceived strength E equal to x times the perceived strength E_0 of the standard S_0 . Or, loosely speaking, S is considered as *subjectively equal* to x times S_0 . Both rating and magnitude scaling principally provide psychophysical dose-response curves, where E is plotted against S .

Pitch can be measured on the **mel scale** by magnitude scaling. Here, a pure tone of 1 kHz at a sound pressure level of 40 dB is taken as the standard that is assigned the pitch value of 1000 mel. A test tone of arbitrary frequency, which appears as x times higher in pitch than the standard tone's pitch, is assigned the value of $x1000$ mel ($0 < x < \infty$). Experiments reveal that the mel scale is monotonically, but not completely linearly, related to the logarithm of the tone's frequency, and that pitch measured in mel slightly depends on the intensity of the test tones.

Loudness can, aside from the rather technical A-weighted dB and phon scales, be measured also by psychological magnitude scaling. This yields the **sone scale**.² The standard stimulus is a tone of 1 kHz at a sound pressure level of 40 dB, which is assigned the loudness of 1 *sone*. A test stimulus can be a steady-state sound of arbitrary spectral intensity distribution. The listener's task is analogous to that in the *mel* scale: A sound is given the loudness x sone if it appears as x times as loud as the standard. The sone scale differs from the phon scale in that all judgments are referred to one standard, not to many standards of different intensities among the tones of 1 kHz, in that the demand of tonality is relinquished, and in that psychological scaling is required (for details, see Chapter 21). The sone scale approximately corresponds to **Stevens' power law**, $E = \text{const}(I/I_0)^b$, where b is a constant value, here about 0.3. Notice that Fechner's law and Stevens' law cannot produce coinciding curves because of the different formulas.

Noisiness is an attribute that may be placed between loudness and annoyance. It refers to temporally extended sounds with fluctuating levels and spectra. An adequate physical description of those stimuli is provided by the **equivalent continuous A-weighted sound pressure level** ($L_{pAeq,T}$). Here, the microphone-based A-weighted sound pressure level is converted into intensity, temporally integrated, and the result averaged over the measurement period T . The

finally achieved value is again logarithmized and multiplied by 10. The unit is called dB. A refinement of the sound pressure's weighting as applied in the "perceived noise level" yields dB measurements the unit of which is called noy.

Annoyance caused by noise refers, as noisiness, to unwanted and/or unpleasant sounds and is mostly attributed to temporally extended and fluctuating sounds emitted, for instance, by traffic, an industrial plant, a sports field, or the activity of neighboring residents. Mainly, the $L_{pAeq,T}$, or other descriptors highly correlating with the $L_{pAeq,T}$ (see Chapter 25), are taken as the metric base, whereby the measurement periods T can range from hours to months. Annoyance with respect to the noise exposition period is explicitly measurable by rating. Sometimes also the percentage of people who are highly annoyed when exposed to a specific sound in a specific situation during the specified temporal interval is determined (for details, see Chapter 25). To achieve dose-response relationships (e.g., mean annoyance ratings in dependency on the related $L_{pAeq,T}$ measurements) of reasonable linearity and minimal error, it is recommended that the annoyance judgments be improved, for instance, by a refinement of the categories offered to the listeners.³ Annoyance quantified in this manner depends, however, besides the sound's intensity, spectral composition, and temporal fluctuation, especially on the non-acoustical context. So, the coefficient of correlation between annoyance ratings from field studies and the corresponding $L_{pAeq,T}$ values seldom exceeds $\frac{1}{2}$. That is to say, the relative part of the variance of annoyance ratings cleared up by physical sound characteristics as given in the $L_{pAeq,T}$ is mostly less than $\frac{1}{4}$. This results in a broad "error band" around the mean dose-response curve. Nevertheless, technical and also political agencies usually assess community reactions to noise exposure solely by the microphone-based $L_{pAeq,T}$ or related descriptors. However, because most of these descriptors correlate with each other close to 1, it does not make much sense to prefer one of them to the others.⁴ It must also be taken as a matter of fact that individual annoyance cannot validly be measured by such an index and that community annoyance is captured by these indices solely through a high degree of aggregation. **Nonauditory context variables influencing sound-induced annoyance** include the time of day the sound occurs, the novelty and meaning the sound carries, and cultural⁵ as well as past personal experiences with that sound. Current theories of annoyance that claim to explain these context effects refer either to the psychological or the biological function of audition. The **psychological function** of the acoustical signals includes (1) feedback related to an individual's sensorimotor actions, (2) identification, localization, and the controllability of sound sources, (3) nonverbal and verbal communication, (4) environmental monitoring, and (5) the tendency to go on alert through inborn or learned signals. Acoustical signals incompatible with, or even severely disturbing, control of

behavior, verbal communication, or recreation, relaxation, and sleep, enforce to break the current behavior. This is considered as the primary effect of noise exposure, followed by annoyance as the psychological reaction to the interruption.⁶ Regarding the **biological function**, the respective theory assumes that annoyance is a **possible loss of fitness signal** (PLOF-signal), which indicates that the individual's Darwinian fitness (general ability to successfully master life and to reproduce) will decrease if she or he continues to stay in that situation. Therefore, especially residents should feel threatened by foreigners who are already audible in the habitat, because that may indicate that there are intruders that are going to exploit the same restricted resources in the habitat. This explains why sounds perceived as man-made are likely to evoke more annoyance than sounds of equal level and spectral composition, but attributed to non-man-made, respectively, natural sources.⁷ Thus, annoyance is considered as the primary effect of noise exposure, which is followed by a distraction of attention from the current activity. That in turn frees mental resources needed for behavioral actions toward the source of the sound. Possible actions are retreating from the source, tackling the source, standing by and waiting for the opportunity to select an appropriate behavior, or simply coping with the annoyance by adapting to the noise.⁸

Ecological psychoacoustics deals, in contrast to traditional psychoacoustics, with real-world sounds that usually vary in frequency, spectral composition, intensity, and rhythm. The main topics can be called auditory analysis and auditory display. Both are restricted to the nonspeech and nonmusic domain.

Auditory analysis treats the extraction of semantic information conveyed by sounds and the construction of an auditory scenery from the details extracted by the listener. Experiments reveal that the incoming sonic stream is first segregated into coherent and partly or totally overlapping discernible auditory events, each identifying and characterizing the source that contributes to the sonic stream. Next, these events are grouped and establish the auditory scene.⁹ A prominent but special example is the discovery that detection and localization of a (moving) source exploits (1) the temporal difference of the intensity onsets arriving at the ears, (2) different prefiltering effects on the sonic waves before they reach the eardrums due to shadowing, diffraction, and reflection properties of the head, auricles, torso, and environment, and (3) the variation of the spectral distribution of intensity with distance.² To acquire such sophisticated skills, infants may need up to 12 years, a fact that should be taken into account if an unattended child below this age is allowed, or even urged, to cross, cycle, or play in the vicinity of places with road traffic.

Auditory display concerns how artificial sounds can be generated to induce a desired auditory scene in the listener. The term covers (1) *auditory icons* suitable for alerts or for the representation of ongoing processes in systems (e.g., in computers and machines), (2) *audification* of originally inaudible periodic signals by frequency shifting into the audible range for humans

(e.g., seismic records), (3) *sonification* of originally nonauditory and nonperiodic events (e.g., radioactivity measured by a Geiger counter), and (4) also *sonic qualification* of nonauditory events or facts (e.g., auditory accentuation of particular visual scenes in movies, or auditory identification of defects in mechanical machines).¹⁰

4 SPEECH COMMUNICATION

The basic capabilities of generation, processing, segregation, and grouping of sonic streams include, as Fig.1 suggests, also **speech production** and **speech perception**. The complicated structure of speech makes this kind of communication susceptible to disturbances at different locations in the transmission path. Instances of such disturbances are *background noise*, *hearing loss*, and *disturbed auditory feedback*.

Speech production can be described as hierarchically organized **multiple parallel-to-serial transformations**.¹¹ Consider, for instance, a keynote speaker trying to transmit an idea. She/he then serializes the idea into sentences, each sentence into words, each word into syllables, each syllable into special speech sounds (phonemes) called vowels (V) and consonants (C), and each phoneme into a particular stream of sound pressure fluctuations, as indicated in the left and middle of Fig.1. Vowels have the character of tones with a low fundamental frequency (men: ~80–160 Hz, women ~170–340 Hz). They are generated by air flowing through adducted vocal folds, which makes them vibrate through the Bernoulli effect, while the vocal tract (pharyngeal plus oral plus nasal cavities) is relatively “open.” This gesture is called *voicing* or *phonation*. The vocal tract forms an acoustic resonator, the shape of which is controlled by the speaker in a manner that concentrates the sound energy into four narrow frequency bands called **formants**. Vowels then differ with respect to the distribution of energy in these formants. Consonants originate if the articulators (lips, tongue, jaw, soft palate) form narrow gaps in the vocal tract while air flows through. This causes broadband turbulence noise reaching relatively high frequencies. Consonants can be voiced or unvoiced, depending on whether or not the broadband signal is accompanied by phonation.¹² General American English includes, for instance, 16 vowels and 22 consonants. In each syllable, a vowel is mandatory that can, but must not, be preceded and/or followed by one or more consonants. Commonly, a person’s speech rate ranges between 4 to 6 syllables per second (see Chapter 22).

In general, a **linguistic stress** pattern is superimposed upon the syllables of an utterance. Stress is realized mainly by enhancing the loudness but can also be expressed by lucidly lengthening or shortening the duration of a syllable or by changing the fundamental frequency. It is the vowel that is manipulated to carry the stress in a stressed syllable. Usually, a string of several words is uttered in a fixed rhythm, whereby the beat coincides with the vowel of the stressed syllables. Linguistic pronouncement (prosody, stress) sustains speech recognition but carries also nonverbal

information, for example, cues informing the receiver about the emotional state of the speaker. An erroneous integration of linguistic stress into an utterance while serializing syllables into strings of phonemes is possibly the origin of stammering.¹¹

Speech perception is inversely organized with respect to speech production and can be described as chained **serial-to-parallel transformations**. Thereby, serial-to-parallel transformation means that a temporal sequence of bits is constricted to an equivalent byte of information that is coded spatially without using the dimension of time. To get back the keynote, the listener, therefore, has at first to constrict distinct parts of the auditory stream into vowels and consonants that have subsequently to be concatenated to syllables. Now, words have to be assembled from the syllables, sentences from the words, and finally the keynote from the sentences. On each processing level, such a **segmentation** has to take place in order to get the units of the next level in the hierarchy. In the flow of speech, therefore, delimiter signals must be embedded that arrange the correct grouping of units on one level into a superunit on the next higher level. In communication engineering, such signals are provided by clock pulses or busy/ready signals. On the word and sentence levels, pauses and the raising/lowering of the fundamental frequency can be used for segmentation. To get syllables from phonemes, the vowel onset, though it is positioned in the middle of a syllable, provides a ready signal because each syllable has just one vowel. Grammatical constraints that generate redundancies, or the rhythm associated with a string of stressed syllables, can additionally be exploited for segmentation on this level. Hence, a distortion in paralleling serial events on an arbitrary level in ongoing speech can seriously hamper the understanding of speech. Referring to written language, it may be that such a deficit is responsible for dyslexia.

Background noise and hearing loss both impair the understanding of speech (see Chapter 22): The noise lowers the signal-to-noise ratio, and also a raised hearing threshold can be considered as equivalent to a lowered signal-to-noise ratio. However, an amplification of the unfiltered speech signal, which just compensates for the noise or the hearing loss, does not suffice to reestablish understandability. The reason is that speech roughly occupies the frequency range between 500 Hz and 5 kHz, but in vowels the sonic energy is almost entirely concentrated in the frequency band below 3 kHz, whereas in voiceless and voiced consonants energy is present also above 3 kHz. It is especially this higher frequency part of the spectrum that is necessary for the discrimination of consonants. Thus, low-pass filtering of speech signals hampers the discrimination of consonants much more than the discrimination of vowels. Since the number of consonants exceeds the number of vowels, and because of the basic C-V-C structure of the syllable, consonants transmit considerably more information than vowels. It follows that high-frequency masking noise, or age-related hearing loss with elevated hearing thresholds especially at the higher frequencies, or cutting off higher

frequencies by a poor speech transmission facility, must severely deteriorate speech recognition since in all three cases nearly exclusively the discrimination of consonants is impaired. A linear increase of an amplifier's gain in a transmission circuit cannot solve the problem. This enhances the intensity also in the low-frequency domain, which in turn broadens and shifts simultaneous and temporal masking toward the higher frequencies. So, the result is even a further decrease of understandability. Therefore, in order to overcome the noise, or the age-related hearing loss, or to help conference participants who often have problems to distinguish the consonants when listening to an oral presentation held in a foreign language in a noisy conference room, the frequencies above 3 kHz should considerably be more amplified than the lower frequencies. Modern hearing aids can even be attuned to meet individual deficits. This is performed by scaling the gain according to the elevation of the hearing thresholds at different frequencies. To avoid a disproportionate loudness recruitment (see Chapter 21), however, the gain must be scaled down, when the intensity attained through the amplification outreaches the threshold intensity.

Disturbed auditory feedback of one's own speech, for instance, through any kind of acoustical noise, or by delayed or frequency-shifted auditory feedback, affects speaking. An immediate reaction to those disturbances is that we usually increase loudness and decrease speech rate. Research, however, revealed that further effects can be observed: If the speech sound is fed back with a delay ranging from 200 to 300 ms (that corresponds to the duration of a syllable), artificial stutter is produced.¹³ Delays in the range from 10 to 50 ms, although not noticed by the speaker, induce a lengthening of the vowel duration of linguistically stressed long syllables of about 30 to 80% of the delay time, whereas vowels of stressed short syllables and of unstressed syllables, and also all consonants, are left unaffected by the delayed feedback. This reveals that linguistic stressing imposes a strong **audio-phonatory coupling**, but solely upon the respective vowel.¹¹ However, the fundamental frequency when stripped of all harmonics by rigorous low-pass filtering does not have any influence on the timing of speech in a delayed feedback setup. In contrast, auditory feedback of the isolated fundamental frequency does influence phonation when the frequency is artificially shifted: It changes the produced frequency with a latency of about 130 ms in the opposite direction, such that at least an incomplete compensation for the artificial frequency shift is reached.¹⁴

All the effects of disturbed auditory feedback reported in the last paragraph indicate that speech production is embedded in different low-level control loops that use different channels hidden in the self-generated sound. We are yet far away from an understanding of the physiological base of these processes.

CHAPTER 20

THE EAR: ITS STRUCTURE AND FUNCTION, RELATED TO HEARING

Hiroshi Wada

Department of Bioengineering and Robotics
Tohoku University
Sendai, Japan

1 INTRODUCTION

The ears are paired sense organs that collect, transmit, and detect acoustical impulses. Each of them is comprised of three main parts: the outer ear, middle ear, and inner ear. Sound waves are focused into the external auditory canal by the fleshy external part of the ear, or pinna. The sound waves in the auditory canal cause vibration of the tympanic membrane, which results in motion of the three small bones, or ossicles, in the middle ear. The motion of the ossicles is transmitted to the cochlea of the inner ear, where it is transformed into vibration of the organ of Corti. This vibration is amplified by the motion of outer hair cells located in this organ. The mechanical motion of the organ of Corti is then transduced into encoded nerve signals by inner hair cells, which are also situated in the organ of Corti, these signals subsequently being transmitted to the brain. For a good understanding of the function of the ear and human hearing, knowledge of the anatomy of the main parts of the hearing organ is required, as is interpretation of how all of these parts function together. Intense noise is of concern because it can cause permanent damage to the hearing mechanism, particularly the hair cells.

2 REMARKABLE SENSITIVITY OF THE EAR

Sound is energy that is transmitted by pressure waves in air and is the objective cause of the sensation of hearing.

Figure 1 Auditory response area for humans. Sound within the dotted area is audible. This area is bounded on one side by the limits of tolerability of sound and on the other side by the limits of detectability. The difference between the two thresholds is quite wide.

Figure 1 shows the auditory response area for humans.^{1,2} Sound within the dotted area is bounded on one side by the threshold of pain and on the other by the threshold of audibility as a function of frequency. The sound pressure level (SPL) difference between these thresholds, that is, the dynamic range, is quite wide, nearly 130 dB at a frequency of 4.0 kHz. High-end recording equipment has a dynamic range of 90 dB. This means that our ears are much more sensitive than such equipment.

3 OVERVIEW OF PERIPHERAL ANATOMY: OUTER, MIDDLE, AND INNER EARS

Figure 2 displays a computer-aided reconstruction of the human middle and inner ears, which was obtained from a fixed temporal bone extracted from a fresh cadaver. The relationship of size and location among the various components of the peripheral auditory system can be clearly understood. In humans, as shown in Fig. 3, the external auditory canal with a diameter of 7 mm and a length of 30 mm, which is slightly bent and elliptical, is terminated by a conical-shaped tympanic membrane with a diameter

Figure 2 Computer-aided reconstruction of the human middle and inner ear, which was obtained from the temporal bone extracted from a fresh cadaver. The relationship of size and location among the various components can be clearly understood.

Figure 3 Human peripheral auditory system. Mammals always have three ossicles, namely the malleus, the incus, and the stapes.

of 10 mm and a thickness of 0.1 mm. Three ossicles, namely the malleus, incus, and stapes, are located in the tympanic cavity. The malleus is attached to the tympanic membrane, the incus lies between the malleus and the stapes, and the stapes is connected to the cochlea.

Figure 4 depicts the human cochlea with a length of 35 mm, which is spiral shaped and has three fluid-filled compartments, that is, the scala vestibuli, the scala media, and the scala tympani. They are separated by Reissner's membrane and the basilar membrane. The scala vestibuli and scala tympani contain perilymph, and the scala media contains endolymph. At the basal end, the scala vestibuli has an oval window, and the scala tympani has a round window. The

Figure 4 Human cochlea and its cross section. The cochlea has three fluid-filled compartments, which are divided by Reissner's membrane and the basilar membrane.

Figure 5 Structure of the organ of Corti. This organ sits on the basilar membrane. Two types of sensory cells, i.e., the inner hair cells and the outer hair cells are located in this organ.

base of the stapes, called the footplate, is sealed by a flexible ligament, and the footplate transmits the vibration of the middle ear to the fluid in the scala vestibuli.

As shown in Fig. 5, the organ of Corti sits on the basilar membrane and contains two types of hair cells, that is, the inner hair cells and the outer hair cells. There are approximately 3,500 inner hair cells and 12,000 outer hair cells in humans.³ Hairlike structures, that is, stereocilia, extend from the top of these cells. The organ of Corti is covered by the tectorial membrane and given rigidity by the pillar cells. There are three types of supporting cells, namely, Deiters', Hensen's, and Claudius' cells.

4 ACOUSTICAL PROPERTIES OF THE OUTER AND MIDDLE EARS

As shown in Fig. 6,⁴ sound pressure amplification at the tympanic membrane is greatest when the frequency is around 4.0 kHz. This amplification is caused by standing waves in the external auditory canal. Figure 7 depicts a simplified model of the external auditory

Figure 6 External auditory canal resonance observed in human subjects. Plotted along the ordinate is the decibel difference between the sound pressure level at the tympanic membrane and that in the sound field at the entrance of the external auditory canal (F). The difference between them is largest at around $f = 4.0$ kHz. [From Weiner and Ross.⁴ Copyright © 1946 by The Acoustical Society of America (ASA). Reprinted by permission of American Institute of Physics (on behalf of ASA).]

Figure 7 Pressure variation in a pipe with one end open and the other end closed when $f_0 = c/4l$, where f_0 is the fundamental resonance frequency, c is the velocity of the air, and l is the length of the pipe.

canal, that is, a pipe with one end open and the other end closed, with pressure variation along the pipe at the fundamental resonance frequency, f_0 . Sound pressure amplification at the end of the pipe is noticeable. Due to this phenomenon, the threshold of audibility is

believed to be the smallest at the resonance frequency of the external auditory canal, which is shown in Fig. 1.

An attempt was made to measure the vibratory responses of guinea pig tympanic membranes using time-averaged electric speckle pattern interferometry.⁵ Figure 8 shows perspective plots of the displacement distribution of the left tympanic membrane vibrations when the displacement at each point reaches its maximum value. The amplitude of tympanic membrane vibrations is of nanometer order of two digits, that is, 10 to 99 nm, when the sound pressure level of the stimulation is between 70 and 85 dB.

The three ossicles transmit sound vibrations from the tympanic membrane to the oval window of the cochlea. The main role of the middle ear is to match the low impedance of the air in the external auditory canal to the high impedance of the cochlear fluids. In other words, the middle ear is an impedance transformer. Without this function, much of the sound energy would be reflected. As shown in Fig. 9, when the tympanic membrane vibrates, the ossicles basically rotate around the axis between the anterior malleal ligament and the posterior incudal ligament, and the umbo and stapes have a pistonlike movement.^{6,7} The area of the tympanic membrane is much larger than that of the stapes footplate. The forces collected by the tympanic

Figure 8 Perspective plots of the displacement distribution of the left tympanic membrane vibrations when the displacement at each point reaches its maximum value: (a) frequency $f = 1.0$ kHz and sound pressure level SPL = 85 dB, (b) $f = 2.5$ kHz and SPL = 70 dB, (c) $f = 3.0$ kHz and SPL = 75 dB, and (d) $f = 4.0$ kHz and SPL = 75 dB. At the frequency of 1.0 kHz, the whole tympanic membrane vibrates in phase. The maximum displacement amplitude is about 30 nm. At the frequency of 2.5 kHz, the tympanic membrane has two local maxima, one in the posterior portion and the other in the inferior portion. The number of the peaks increases and the vibration mode becomes complicated with an increase in the frequency. [From Wada et al.⁵ Copyright © 2002 by The Acoustical Society of America (ASA). Reprinted by permission of American Institute of Physics (on behalf of ASA).]

Figure 9 Dynamic behavior of the middle ear. Arrows indicate the directions of the movements. The ratio of the area of the tympanic membrane to that of the stapes is 17 : 1, and the ratio of the arm of the malleus to that of the incus is 1.3 : 1.0.

Figure 10 Traveling waves on the basilar membrane obtained from the finite element method model: (a) input stimulus frequency $f = 6.0$ kHz, and (b) $f = 2.0$ kHz. Traveling waves on the basilar membrane have a peak near the base when high-frequency sound enters the cochlea, while low-frequency sound develops the traveling waves on the basilar membrane, which have a peak near the apex.

membrane, therefore, increase the pressure at the oval window. The arm of the malleus is larger than that of the incus, and this produces leverage, which increases the pressure and decreases the velocity at the stapes. By this mechanism, more than 30% of the sound energy reaches the cochlea.

5 COCHLEAR FUNCTION: TRAVELING WAVES ALONG THE COCHLEAR PARTITION, THE MECHANO-RECEPTOR-TRANSDUCTION ROLE OF HAIR CELLS, RECENT DISCOVERY OF HAIR CELL MOTILITY, AND THE "COCHLEAR AMPLIFIER" AND OTOACOUSTIC EMISSIONS

Vibrations of the stapes generate movement of the cochlear fluids that interacts with the basilar membrane, the stiffness of which decreases from base to

Figure 11 Place-characteristic frequency map for humans. High- and low-frequency components of sound are analyzed in the basal and apical regions of the cochlea, respectively.

apex. This interaction produces progressive traveling waves on the basilar membrane,⁸ which are similar to waves beating upon a seashore. Figure 10 depicts these traveling waves.⁹ When sound is transmitted to the basilar membrane, the position of the maximum displacement amplitude of its vibration is related to the frequency of the sound. In other words, each position along the basilar membrane has a maximum displacement amplitude at a specific frequency called the characteristic frequency. Figure 11 is a frequency map for

Figure 12 Vibration mode of the organ of Corti: (a) displacement toward the scala vestibuli, (b) resting position, and (c) displacement toward the scala tympani. The inner hair cell stereocilia are deflected by the flow of fluid caused by shear motion between the tectorial membrane and the reticular lamina. [From Wada et al.¹¹ Copyright © 2002 by Elsevier. Reprinted by permission of Elsevier.]

humans showing characteristic frequencies at different positions in the ear.¹⁰ As shown in Fig. 12, when sound enters the ear, the organ of Corti, which sits on the basilar membrane, undergoes a rocking motion. Although the details of cochlear operation are unclear, one possible mechanism is that basilar membrane displacement toward the scala vestibuli produces shear motion between the tectorial membrane and the reticular lamina and induces the flow of fluid in the direction of the arrow, which leads to the deflection of the free-standing inner hair cell stereocilia in the same direction as the flow.¹¹ This deflection induces the opening of ion channels and an influx of ions into the inner hair cell, thus releasing the transmitter. As a result, pulses are generated in the auditory nerve fibers, as shown in Fig. 13. Because of this mechanism, we can hear sound.

As depicted in Fig. 14, the mammalian outer hair cell is cylindrical shaped with a radius of 4 to 5 μm and a length of 30 to 90 μm . It is capped by the cuticular plate with stereocilia at one end and by the synaptic membrane at the other end. When the stereocilia bend in the direction of the arrow, K^+ ions flow into the cell and depolarize the membrane potentials. At the same time, the outer hair cell contracts. By contrast, when the stereocilia bend in the direction opposite that of the arrow, the membrane potentials are hyperpolarized and the outer hair cell elongates.¹² Figure 15 depicts an experiment where, instead of bending stereocilia, intracellular potentials are changed by the whole-cell voltage-clamped technique. Experiments reveal that the input-output function of the outer hair cell is not expressed by a straight line but a curved one, that is, the function is nonlinear, which is responsible for compressive nonlinear responses of the basilar membrane¹³ and the cochlea.¹⁴ Moreover, the outer hair cells are under efferent control.¹⁵

Figure 13 Response in the auditory nerve fiber. The upper waveform is an example of spontaneous activity. When a stimulus tone is delivered to the external auditory canal, the spike rate rises with an increase in the stimulus level.

Figure 14 Schematic diagram of the outer hair cell. The polarity is the same as that of Fig. 12. The cell is capped by the cuticular plate with stereocilia, which have a V- or W-shaped formation.

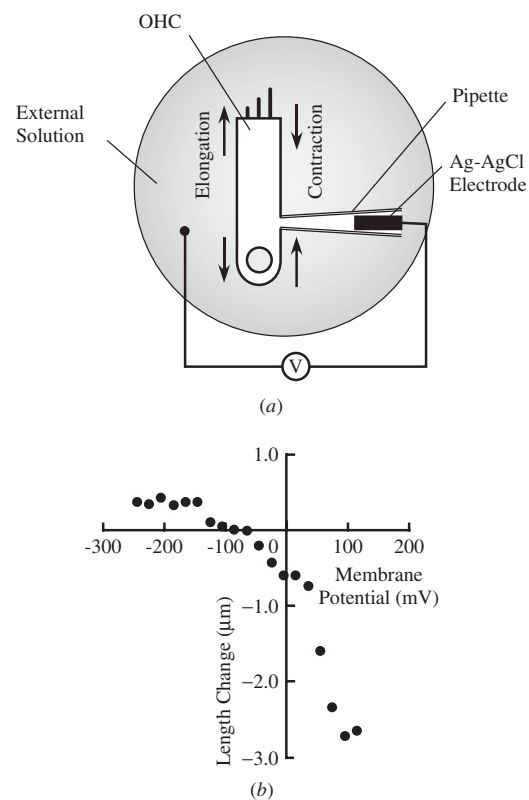

Figure 15 Measurement of outer hair cell motility. (a) Whole-cell voltage clamp technique. To elicit mechanical movements of the outer hair cells, step and sinusoidal voltage stimuli are given to the isolated outer hair cells. (b) Length change of the outer hair cell in response to step voltage stimuli. The positive and negative directions show cell elongation and contraction, respectively.

As shown in Fig. 12, when the organ of Corti is deflected toward the scala vestibuli, the outer hair cell stereocilia bend due to the shear motion between the tectorial membrane and the reticular lamina because the tallest outer hair cell stereocilia adhere to the tectorial membrane. Simultaneously, the outer hair cells contract. Deflection of the organ of Corti toward the scala tympani leads to elongation of the outer hair cells. This repeated contraction and elongation of the outer hair cells, that is, the motility of the outer hair cells, magnifies the deflection of the organ of Corti. To confirm this cochlear amplification, an attempt was made to directly measure the basilar membrane vibrations in both living and dead guinea pigs by a laser Doppler velocimeter.¹⁶ Figure 16 clearly shows that amplification of the basilar membrane vibrations occurs when an animal is alive. The magnified deflection of the organ of Corti leads to increases in the movement of the fluids in the space near the stereocilia of the inner hair cells and in the deflection of the inner hair cell stereocilia. Owing to the mechanism mentioned above, our auditory system is characterized by high sensitivity, sharp tuning, and compressive nonlinearity.¹⁷⁻¹⁹

Recently, an interesting phenomenon, termed otoacoustic emissions, that is, sound that comes from the healthy ear, was discovered.²⁰ Otoacoustic emissions are low-intensity sound generated within the normal cochlea and emitted to the external auditory canal, either spontaneously or in response to acoustical stimulation. Figure 17 shows examples. As shown in Fig. 18, simultaneous measurement of distortion product otoacoustic emissions and basilar membrane velocity was carried out.¹⁶ Clear peaks can be seen on both the spectrograms of the acoustical and basilar membrane velocity measurement at $f = 2f_1 - f_2 = 9.40$ kHz. This result confirms that otoacoustic emissions sensitively reflect the dynamic behavior of the basilar membrane. The origin of otoacoustic emissions is thought

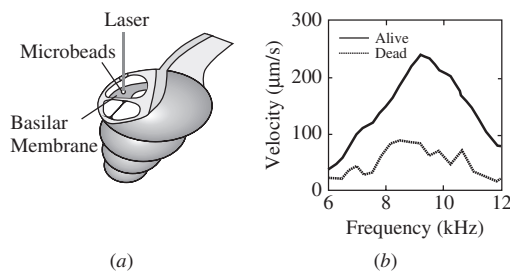

Figure 16 Direct measurement of basilar membrane vibrations in a guinea pig. (a) Measurement procedure. A hole with a diameter of 0.5 mm is opened at the bony wall of the cochlea, and glass microbeads with a diameter of 20 μm are placed on the basilar membrane in order to increase reflections of the laser beam. (b) The basilar membrane velocity responses to periodic tone. SPL = 75 dB. The basilar membrane vibrations are amplified when an animal is alive.

Figure 17 Examples of otoacoustic emissions. (a) Spontaneous otoacoustic emissions of a guinea pig. Narrow-band signal at 1.43 kHz disappears 50 s after the respirator is stopped and reappears 2 min after the end of hypoxia. (b) Distortion-product otoacoustic emissions of a human. When two primary stimuli at levels $\text{SPL}_1 - \text{SPL}_2 = 70$ dB and $f_1 = 1125$ Hz and $f_2 = 1434$ Hz are given to the external auditory canal, a cubic distortion product at the frequency $2f_1 - f_2 = 816$ Hz is detected. It is believed that the nonlinear characteristics of the outer hair cell motility are responsible for generating such distortion. Interestingly, the level of the cubic distortion is greatest when the frequency ratio among $2f_1 - f_2$, f_2 , and f_1 is equal to that of a chord, e.g., do, mi, and so.

Figure 18 Frequency analysis of the outputs: (a) acoustical signal, and (b) basilar membrane velocity. Stimulus levels SPL_1 and SPL_2 of the primaries were 75 and 65 dB, respectively, and stimulus frequencies were $f_1 = 12.55$ kHz, $f_2 = 15.70$ kHz and $2f_1 - f_2 = 9.40$ kHz. Peaks are clearly seen in both the acoustical signal and basilar membrane velocity at 9.40 kHz. [From Wada et al.¹⁶ Copyright © 1997 by World Scientific Publishing. Reprinted by permission of World Scientific Publishing.]

to be the motility of the outer hair cells.²¹ Recently, this technique has been applied to neonatal hearing screening.²²

6 BRIEF SUMMARY OF CENTRAL AUDITORY NERVOUS SYSTEM: ANATOMY AND FUNCTION

Figure 19 shows the ascending auditory pathways. Although their functions remain unclear, some of them are introduced as follows: The cochlear nucleus is comparable to a switchboard and distributes auditory information to several different areas in the auditory pathways; the nucleus of the superior olive compares differences in the timing and loudness of the sound in each ear, and this function is essential for determining the location of sound; the inferior colliculus analyzes changes in the spectrum of sound such as amplitude and frequency modulation and contributes to the quality of sound.²³

Efferent auditory pathways parallel the afferent pathways and descend from the cortex to the hair cells.

Although their functions are still not well understood, they are thought to improve the detection of signals in noise, protect our auditory system from noise damage, and be involved in attention.²⁴

As displayed in Fig. 20, an impressive feature of the auditory cortex is its tonotopic organization, that is, information about the vibrations at different locations along the basilar membrane is relayed to the auditory cortex by fibers. Although the general functions of the auditory cortex are still uncertain, it is particularly sensitive to transients in acoustical signals and thus is considered to be necessary for short-term memory and the analysis of complex sound.²⁵

7 NOISE-INDUCED HEARING LOSS

Noise-induced hearing loss is correlated with noise exposure and is the by-product of modernization. Exposure to moderate loud noise causes temporal hearing loss, which is later recovered. By contrast, exposure to severe loud noise causes permanent hearing loss. There is a consensus that the risk of

Figure 19 Auditory pathways of the brainstem: (a) lateral view and (b) anterior view. Fibers from the cochlea ascend to the cochlear nucleus, the nucleus of the superior olive, the inferior colliculus, and the medial geniculate body, and terminate in the auditory cortex.

Figure 20 Tonotopic organization of the auditory cortex in guinea pigs: (a) measurement area, and (b) schematic representation of the layout of the isofrequency areas. Low and high best frequencies are represented rostrally and caudally, respectively, and isofrequency lines are organized at right angles to the line showing the increase in frequency.

Figure 21 Excess risk as a function of sound pressure level for subjects 65 years of age with an exposure duration of 45 years. Excess risk is defined as the percentage of individuals with hearing handicap among individuals exposed to daily 8-h occupational noise exposure. [From Prince et al.²⁸ Copyright © 1997 by The Acoustical Society of America (ASA). Reprinted by permission of American Institute of Physics (on behalf of ASA).]

Figure 22 Scanning electron microscope study of missing and disarrayed outer hair cell stereocilia of the guinea pig after noise exposure at an SPL of 100 dB SPL for 8 h per day for 3 consecutive days: *, missing; #, disarrayed. Not only sporadic missing outer hair cell stereocilia but also disarrayed outer hair cell stereocilia are observed. By contrast, no loss of the inner hair cell stereocilia is apparent. [From Hou et al.³⁰ Copyright © 2003 by Elsevier. Reprinted by permission of Elsevier.]

noise-induced hearing loss significantly increases with chronic exposure to noise above A-weighted 8-h time-weighted average sound pressure level of 85 dB (Fig. 21).^{26–28} The degree of hearing loss depends not only on the intensity of the noise but also on

Figure 23 Relationship between the tuning curve of auditory nerve fibers and the damage of outer and inner hair cells. —, both cells are intact; ---, total loss of the outer hair cells; ···, disarray of the inner hair cell stereocilia. Damage to the outer hair cells results in both elevation of threshold and loss of the tuning-curve tip. On the contrary, damage to the inner hair cell stereocilia results in only elevation of the threshold.

the duration of noise exposure. It also has individual variations.²⁹

When sensory cells are exposed to moderate noise, the stereocilia of the outer hair cells are more easily damaged than those of the inner hair cells, which is shown in Fig. 22.³⁰ Furthermore, severe noise destroys the hair cells. As shown in Fig. 23, high sensitivity and sharp tuning of our hearing are lost when the outer hair cells are damaged, while sensitivity is reduced when stereocilia of the inner hair cells are partially damaged.³¹ When the inner hair cells are completely destroyed, we become almost deaf.

8 CONCLUSIONS

An anatomical and functional overview of the human auditory system was herein presented, the main conclusions being as follows: High sensitivity and sharp tuning of our auditory system originate in the motility of the outer hair cells located in the organ of Corti in the cochlea, and the input–output function of the outer hair cell motility governs the nonlinearity of our auditory system. For those who would like to know more about our auditory system, well-written textbooks^{32–35} are recommended. Furthermore, conference proceedings^{36–38} are recommended for those who are interested in recent developments in this area.

CHAPTER 21

HEARING THRESHOLDS, LOUDNESS OF SOUND, AND SOUND ADAPTATION

William A. Yost
Parmly Sensory Sciences Institute
Loyola University
Chicago, Illinois

1 INTRODUCTION

This chapter covers three important aspects of auditory perception: thresholds of hearing, loudness, and sound adaptation. Thresholds of hearing represent an estimate of the softest sounds the average human can detect, and these thresholds form the basis of the fundamental measure of hearing loss, the audiogram. Thresholds of hearing vary as a function of signal frequency and signal duration. Changes in many different physical aspects of sound may lead to the perception that the sound's loudness has changed. Loudness level measured in phons and based on equal loudness contours and loudness measured in sones using subjective scaling procedures are the two most common measures of subjective loudness. Sounds that are presented for long periods exhibit several perceptual phenomena including threshold shifts and various forms of adaptation. Long-duration, intense sounds can cause either a temporary or a permanent loss of hearing as measured by an increase in the threshold for detecting sound. The loudness or other perceptual aspects of sound can change as a function of prior exposure to sounds of long duration leading to various forms of auditory adaptation.

2 THRESHOLDS OF HEARING

A fundamental measure of the auditory system is the determination of the softest sounds that a person can detect. The threshold of hearing is measured as a function of the frequency of pure tones presented to subjects asked to detect tones that are presented at levels that are just detectable in a quiet and calibrated test environment. Thresholds of hearing are often used to determine a test subject's hearing loss and the frequency region in which that hearing loss occurs. When thresholds of hearing are used to determine hearing loss, the threshold measurements are often referred to as the audiogram.

In general, thresholds of hearing are measured by determining the sound pressure level of a tone presented at a specified frequency (often octaves of 125 Hz) that a subject indicates renders the tone just barely noticeable or detectable. The behavioral method for obtaining thresholds of hearing, the methods for calibrating the sound pressure level presented to the subject, and the hearing thresholds have been standardized [see American National Standards Institute (ANSI) and the International Organization

for Standardization (ISO) standards listed in the reference section]. The test tones can be presented over headphones of different types (e.g., supraaural and insert) or from a loudspeaker in the free field. A supraaural headphone has a cushion that fits over the pinna and the headphone speaker rests on the outside of the outer-ear canal. An insert phone has its earphone loudspeaker located within the outer-ear canal, usually in a pliable mold that seals the outer-ear canal. In all cases accurate estimates of the thresholds of hearing require that the test environment be as noise free as possible and conform to the specifications of the ANSI standard for American National Standard Maximum Permissible Ambient Noise Levels for Audiometric Test Rooms (1999).

If the thresholds of hearing are measured in the free field when the tones are presented from a loudspeaker, the thresholds are referred to as minimal audible field (MAF) thresholds. For a MAF estimate of the thresholds of hearing, the loudspeaker is located on the same plane as the listener's pinna, directly in front of the listener, 1 m from the location of the listener's pinna, and the listener uses both ears (binaural listening) in the detection task. The level of the tone at each frequency is calibrated using a microphone placed at the location of the listener's tympanic membrane (eardrum), but with the listener not in the room.

If the thresholds are measured via headphone presentations, then the thresholds are referred to as minimal audible pressure (MAP) thresholds. The level of the tones in the MAP procedure is calibrated by measuring the sound pressure level at each test frequency within an acoustic coupler fitted to the headphone. The acoustic coupler is standardized [ANSI 3.7–1995 (R2003), ANSI 3.25–1989 (R2003)] to provide a reasonable approximation of the acoustic properties of the outer ear so that the sound pressure level provided by the headphone is that which would occur at the tympanic membrane of an average listener. Acoustic couplers for supraaural phones measure the sound pressure in a volume of 6 mL, which is the approximate average volume of the outer-ear canal. Acoustic couplers for insert phones measure the sound pressure level in a volume of 2 mL, since 2 mL is the approximate average ear canal volume between the tip of the insert earphone and the tympanic membrane. Several different headphone and acoustic coupler combinations can be used to calibrate thresholds in MAP procedures. Such thresholds are referred to as

reference equivalent threshold sound pressure levels (RETSPLs).

A standardized psychophysical procedure is required to obtain accurate estimates of thresholds [ANSI 3.21–1978 (R1997)]. The accepted method is a method of limits procedure in which the level of the tone starts well above the threshold level, and then the level is decreased until the listener indicates that the tone is no longer detectable. Then the tonal level is increased and decreased from this initial estimate of threshold to estimate the final threshold level that would yield the tone as detectable 50% of the time. This procedure is repeated for each tonal frequency that is tested. Several other psychophysical procedures have also been used to measure thresholds of hearing [ANSI 3.21–1978 (R1997)].

Figure 1 and Table 1 present average standardized thresholds of hearing for listeners with normal hearing for the MAF and MAP procedures (ANSI S3.6–1996). The thresholds are expressed as MAF or MAP RETSPL thresholds of the sound pressure level (SPL, dB). The reference sound pressure for measuring decibels of sound pressure level is 20 μ Pa. Thus, as can be seen in Fig. 1 and Table 1, thresholds of hearing are lowest in the frequency region between 500 and 4000 Hz at about 0 dB, so that 20 μ Pa is approximately the smallest sound pressure detectable by the human auditory system. At this small pressure, it has been estimated that the tympanic membrane

Figure 1 Thresholds of hearing in decibels of sound pressure level (dB SPL) are shown as a function of frequency (MAF) for six conditions: RETSPL minimal audible field (MAF) thresholds, RETSPL-MAP thresholds for a supraaural phone and 6-mL coupler, RETSPL-MAP thresholds for a supraaural phone and an artificial ear, RETSPL-MAP thresholds for an insert phone and a Zwischlocki coupler, thresholds for pain, and thresholds for discomfort. The RETSPL measures are from ANSI 3.6–1996. The thresholds for pain and discomfort represent estimates of the upper limits of sound pressure level that humans can tolerate. See Table 1 for additional details about the headphones and couplers used for these thresholds. (Based on ANSI standards and adapted from Yost.¹² Reprinted by permission.)

Table 1 Thresholds of Audibility for a Number of Testing Condition

Frequency (Hz)	MAF ^a	Thresholds—RETSPL (dB SPL)		
		Supra-aural ^b	Circumaural ^c	Insert ^d
125	22	45	29.5	26
200	14.5	32.5	—	18

is displaced a distance equal to approximately the diameter of a hydrogen atom. The thresholds of hearing indicate that human listeners can detect tones over the frequency region from approximately 20 to 20,000 Hz, but the thresholds are elevated for low and high frequencies relative to those in the middle frequencies within this range. The loss of sensitivity at the low and high frequencies is partially attributable to the transfer function of the outer and middle ears as well as limitations placed on the transduction of sound pressure and vibration into neural impulses that occurs within the inner ear.

Figure 1 and Table 1 indicate that the actual thresholds of hearing differ depending on how the tones are presented, that is, if they are presented over loudspeakers or from different headphone types. These differences exist despite the attempt to provide calibration procedures that might be thought of as ensuring that the thresholds represent the actual sound pressure level being delivered to the auditory system (i.e., to the tympanic membrane). However, differences in the measured thresholds exist despite the calibration procedures. Almost all of the differences in thresholds of hearing obtained across the various MAF and MAP procedures can be explained by taking into account the diffraction of sound around the head and pinna that occurs in several of the procedures and the exact

resonant and impedance properties of the outer ear.¹ Making exact estimates of the thresholds of hearing at frequencies higher than approximately 8000 Hz are complicated by the resonance properties of the outer-ear canal.

The thresholds of hearing also depend on the duration of the tone being presented. The thresholds in Fig. 1 and Table 1 represent thresholds in dB SPL for tones whose durations are 500 ms or longer. The thresholds of hearing increase as the duration of the tones decrease, and the exact nature of the increase in the thresholds of hearing with decreasing duration is frequency specific. For tonal frequencies less than approximately 1000 Hz, thresholds of hearing increase about 10 dB for each 10-fold decrease in tone duration below about 200 to 300 ms (i.e., maintaining the tonal level at threshold at approximately constant energy). However, the rate of increase in thresholds as duration decreases for tones whose frequencies are greater than 1000 Hz is less than that for tones whose frequencies are less than 1000 Hz.²

As the sound pressure level increases to large values human listeners will experience discomfort or pain, indicating that the levels are reaching the upper limit that the auditory system can tolerate. The upper curves in Fig. 1 indicate various estimates of the upper limit of audibility such that tones presented at these frequencies and levels will produce pain or discomfort. The decibel difference between the thresholds of hearing and the upper limits of audibility suggest that the dynamic range for hearing can be as large as 130 dB in the 1000-Hz region of the audible spectrum, and the dynamic range decreases as frequency increases or decreases from this region.

The auditory system can be stimulated either via sound traveling through the outer-ear canal and middle ear to the inner ear or via sound causing the skull to vibrate, which in turn stimulates inner-ear structures to signal the presence of sound. Thus, vibration of the skull (bone vibration), which bypasses the outer and middle ears, can lead to the sensation of sound. Since sound produced by bone vibration bypasses the normal air conduction means of delivering sound to the inner ear, differences between the thresholds of hearing for air conduction as opposed to bone conduction are used to diagnosis problems in the outer and, especially, the middle ear. Just as there are standardized methods and thresholds for air-conducted sound, so are there standardized methods and thresholds for bone-conducted sound [ANSI 3.6–1996 and ANSI 3.13–1987 (R2002)]. The level of sounds necessary to yield bone-conducted thresholds are considerably higher (60 dB or higher) than those obtained for air-conducted thresholds.

3 LOUDNESS OF SOUND

As the level of a sound changes, one usually reports that its loudness has changed. The standard definition of loudness [ANSI 3.20–1995 (R2003)] is: “Loudness is that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from soft to loud.” As such loudness is a subjective

attribute of a sound’s magnitude, as opposed to sound pressure level that is an objective or physical measure of sound magnitude. While the loudness of a sound varies as a function of changes in sound pressure level, loudness can also vary when other physical properties of a sound are changed such as frequency or duration. That is, subjective sound loudness is correlated with sound pressure level, but also with many other physical aspects of sound (e.g., frequency, bandwidth, duration).

Loudness is measured in two ways: as loudness level in phons and loudness in sones. Loudness level is measured in a loudness matching procedure in which two sounds are presented: the standard sound, which is a 1000-Hz tone presented at a particular level expressed in dB SPL, and the comparison (test) sound, presented at a particular tonal frequency (or a noise presented with a particular bandwidth). The listener adjusts the level of the comparison sound so that it is judged equal in subjective loudness to that of the standard sound. Figure 2 shows a few standardized equal-loudness contours obtained using this loudness matching procedure for different levels of the standard, 1000-Hz tone, and different tonal frequencies of the comparison sound (ISO 226:2003 Acoustics). All comparison tones presented at the level and frequency shown on an equal-loudness contour are judged equal in loudness and equal in loudness to a 1000-Hz tone presented at the level shown on the equal-loudness contour. If the level of the 1000-Hz standard was 40 dB SPL, then all of the comparison tones shown on the equal-loudness contour are judged equally loud to this 40-dB, 1000-Hz standard tone, and they are defined as having a loudness level of 40 phons. Thus, the loudness level of a sound of x phons

Figure 2 Equal loudness contours showing the level of a comparison tone required to match the perceived loudness of a 1000-Hz standard tone presented at different levels (20, 40, 60, 80, and 100 dB SPL). Each curve is an equal loudness contour. [Based on ISO standard (ISO 226:2003 Acoustics) and adapted from Yost.¹² Reprinted by permission.]

is the level of the sound required for that sound to be judged equally loud to a 1000-Hz tone presented at x dB SPL. A sound with a loudness level of 40 phons would be judged very soft. There are standard methods and calculations for determining the loudness level of tones and noises [ISO 226:2003 Acoustics and ANSI S3.4-1980 (R 1997)].

The 40-dB equal-loudness contour (i.e., 40-phon contour) is the basis of the weighting used in the definition of the A-weighted sound pressure level measure. If a sound is filtered by a filter whose transfer function is similar to the inverse of the 40-phon contour, the overall sound pressure level in decibels at the output of this filter when referenced to 20 μ Pa is defined as the A-weighted sound pressure level. That is, the overall level of a sound whose spectral components are weighted (filtered) so the high and low frequencies are attenuated as indicated by the inverse of the 40-phon equal-loudness contour known as the A-weighted sound pressure level. The 70-dB equal-loudness contour is used in the same way to determine the weightings for the C-weighted sound pressure level [see ANSI S1.8-1989 (R 2001)].

The loudness of a sound measured on the sone scale is determined from a loudness scaling procedure. While this procedure has not been standardized like that for the phon scale, the loudness of sounds has been measured in many different studies using different scaling procedures.³ In a scaling procedure used to measure sones, a standard tone of 1000 Hz and 40 phons is compared to a comparison (test) sound. The listener in the loudness scaling task is asked to determine the level of the comparison sound in terms of a ratio, namely by judging the comparison sound as x times ($0 \leq x \leq \infty$) as loud as the standard tone. By anchoring the resulting scale at 1 sone when the comparison sound is judged equal in loudness to the 40-phon standard, a numerical scale of loudness is obtained (see Fig. 3). Thus, a sound of y sones is one judged to be y times as loud as a sound that has a loudness of 40 phons (e.g., a sound with a loudness of 3 sones would be judged to be three times as loud as a 40-phon sound).

Above a given threshold value, there is a relatively linear relationship between log sones and level in decibels. The sone scale at 1000 Hz indicates that an increase or decrease in sound pressure level of 10 dB results in a judgment of that sound being twice or half as loud, respectively, that is, a doubling or halving of loudness equals an approximately 10-dB change in sound pressure level. In other contexts^{3,4} the growth of loudness is expressed as a power function of sound intensity, for example, $L = I^{0.3}$, where L equals perceived loudness, I equals sound intensity (e.g., in W/m^2), and the common exponent for such a loudness relationship is approximately 0.3.

When sounds are presented to both ears (sounds presented binaurally), loudness often increases over that measured when the sound is presented to only one ear. In this case, there is evidence for binaural loudness summation. Binaural loudness summation can vary from essentially no binaural summation up to 10 dB, depending on the stimulus and measurement conditions.^{5,6}

Figure 3 (a) Schematic depiction of loudness in sones of a 1000-Hz tone as a function of the level of the tone (dB SPL). The slope of the function indicates that approximately a 10-dB change in level is required to double loudness. 3.(b) Curve A represents the loudness curve from (a) curve B represents the perceived loudness of a 1000-Hz tone masked by a wideband noise (for a person with a hearing loss). Curve B with the steeper slope shows loudness recruitment. (Adapted from Yost¹² and Steinberg and Gardner.¹³ Reprinted by permission)

4 LOUDNESS RECRUITMENT

If a person has a hearing loss or is listening to a sound masked by other sounds, then the threshold for detecting that sound will be elevated as compared to that measured for a person without a hearing loss or in the absence of the interfering sounds. Yet, in these types of conditions the level of the sound judged to be painful or uncomfortable will be the same as that obtained for a person without a hearing loss or without the presence of interfering sounds. Thus, the growth of loudness between threshold and the upper limit of audibility as indicated by the thresholds for pain or discomfort will be steeper for the person with a hearing impairment or detecting tones in the presence of interfering sounds as compared to a person without a hearing loss or detecting a sound in the absence of interfering sounds (see Fig. 3). The increase in the slope of loudness in these circumstances is often referred to as “loudness recruitment” and most

people with a sensorineural hearing loss show such a recruitment of loudness.

Since the measurement of recruitment involves the determination of the thresholds of hearing, a theoretical issue concerning the slope of the recruitment function arises in terms of what the loudness of a sound is at its hearing threshold.⁷ One argument is that the loudness of sound at its threshold is zero. However, other theoretical arguments and measurements suggest that while the loudness of a sound at its threshold is low, it is not exactly zero.⁷

5 PERMANENT AND TEMPORARY THRESHOLD SHIFTS

Long exposure to sound has several different effects on auditory function and on perception. Such exposure to sound can elevate the thresholds of hearing permanently or temporarily, or the exposure can influence the subjective loudness and perception of the sound or other sounds.

Exposure to very intense sounds or somewhat less intense sounds of long duration can cause an elevation of the thresholds of hearing after the intense sound has ceased. A permanent hearing loss results when these elevated thresholds become permanent. But even if exposure to loud sounds does not cause a permanent hearing loss or a permanent threshold shift (PTS), such exposures may lead to a temporary elevation of the thresholds of hearing or a temporary threshold shift (TTS). TTS can exist for just a few minutes after exposure to intense sound, or such threshold shifts can exist for days if not weeks. However, the hearing thresholds of someone experiencing TTS will eventually recover to the thresholds existing prior to the exposure, as long as the person is not exposed to other intense sounds in the intervening period. The length of recovery is directly related to the nature of the noise exposure in the recovery period.

With respect to PTS, there is a trade-off between the level of the exposing sound and its duration. The levels and durations that can cause auditory damage and, thus, lead to PTS are referred to as damage risk criteria (DRC). Table 2 indicates the DRC from the National Research Council's (NRC) Committee on Hearing, Bioacoustics, and Biomechanics (CHABA). The NRC-DRC indicates that if a person is exposed repeatedly (over the course of years) to sounds of these levels and duration, they will most likely experience PTS. Organizations such as the Occupational Safety and Health Administration (OSHA) use various DRCs to limit noise exposure in the workplace. PTS is usually associated with the loss of hair cells in the inner ear. Inner-ear hair cells transduce the pressure and vibrations of the inner ear into the neural-electrical signals used by the auditory system. Other standards have been generated to estimate the levels of sound that may lead to PTS [e.g., ISO 1999: 1990 and ANSI S3.44-1996 (R2001)].

Several variables affect the amount and duration of TTS that one experiences following loud sound exposure. The greatest amount of TTS occurs when the frequency of the sound used to measure TTS is the same or slightly higher than the frequency

Table 2 Damage Risk Criteria (DRC) from the Committee on Hearing, Bioacoustics, and Biomechanics (CHABA) of the National Research Council (NRC)^{a,b}

Duration in Hours	A-weighted Sound Pressure Level
8	90
6	92
4	95
3	97
2	100
1	105
1/2	110
1/4 or less	115

^a Repeated exposure to these sound pressure levels for these durations would lead to a permanent threshold shift.

^b Note: When the daily noise exposure is composed of two or more periods of noise exposure at different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of $C_1/T_1 + C_2/T_2 + \dots + C_n/T_n$ exceeds unity, then the mixed exposure should be considered to exceed a permissible DRC. C_n indicates the total time exposure at a specified noise level, and T_n indicates the total time of exposure permitted at that level according to the DRC listed in the table. For instance, if one was exposed to 6 h (C_1) at 95 dB and 2 h (C_2) at 100 dB, the permissible time periods were 4 h (T_1) and 2 h (T_2). The sum is $6/4 + 2/2 > 1.0$, so this combined exposure exceeds the DRC.

of the exposing sounds. In general, the longer the exposing sound is, the greater the TTS is and the longer the recovery time from TTS. If one is exposed to a wideband sound, then most TTS occurs in the frequency region between 2000 and 6000 Hz, except when the exposure is at high levels and then TTS is greatest for all frequencies above about 2000 Hz. The occurrence of TTS is highly correlated with damage to various structures within the inner ear, but an exact cause of TTS is not known. Because of the difficulty of studying PTS directly in human subjects, measures of TTS are often used to infer or predict what type of sound exposures may cause permanent hearing loss.

6 LOUDNESS ADAPTATION

There are several perceptual effects that occur when one is exposed to an intense sound (but not a sound intense enough to produce TTS or PTS) for periods of many seconds to minutes. Loudness adaptation or perstimulatory fatigue occurs when the subjective loudness of a sound decreases as the exposure to the sound increases. That is, if one is exposed to a moderately intense sound for a few minutes, the loudness of the sound may fade. Such loudness adaptation is usually measured by asking listeners to match the loudness of a test sound to that of exposing sound that has been presented for several seconds or longer. The alternating binaural loudness balance (ABLB) procedure is a typical method used to measure loudness adaptation. The exposing sound at

one ear alternates over time with the comparison sound presented to the other ear. The listener adjusts the level of the test sound at one ear to match the subjective loudness of the exposing sound at the other ear. After presenting the exposing sound for several seconds or longer, the level of the test sound judged to be equal in loudness to the exposing sound decreases. The decrease in the test sound indicates that the loudness of the exposing sound decreases over time, suggesting that the auditory system adapts to the continuous presentation of the exposing sound. The decrease in loudness (i.e., loudness adaptation) ranges from a few decibels to 20 or more depending on the parameters of the exposing sound.

In some cases involving high-frequency tones (frequencies higher than 8000 Hz), loudness adaptation can be complete (leading to complete tone decay) in that after being exposed to the high-frequency tone for a few minutes the tone is no longer perceived as being present.⁸ In such cases, any small change in the exposure is likely to restore the sensation of the high-frequency tone. In most other cases, the loudness of a sound may decrease from a few decibels to 20 or more as a function of loudness adaptation and the decrease in loudness is greater the longer the exposure (adaptation).

Such adaptation effects can determine the perceived loudness of sounds measured in different contexts. One such contextual effect on loudness is loudness recalibration.⁹ Loudness recalibration can be either a perception of increased loudness (loudness enhancement) or decreased loudness (loudness assimilation) due to the context of other sounds presented around the same time as the sound whose loudness is being judged. For instance, if an intense tone of one frequency (f1) is followed by relatively less intense tones: one at the same frequency (f1) and another at a different frequency (f2), the resulting loudness perception is that the less intense tone at f1 is softer than if it had not been preceded by the intense sound.¹⁰ This is like loudness adaptation in that intense sounds make less intense sounds softer, but less intense sounds do not make intense sounds louder. Such recalibration effects exist even when the recalibrating sounds are not of long duration (as occurs for perstimulatory fatigue). These contextual effects make the estimate of the loudness of sounds complicated in that loudness estimates appear to depend on the acoustical context in which a sound's loudness is to be judged.

Other forms of sound adaptation lead to auditory illusions. Such illusions occur when listeners are exposed to an adapting stimulus for a long period (a few minutes). Following the adaptation exposure, the listeners are presented a test stimulus, and the test stimulus is perceived as having attributes that are not a part of the physical stimulus. For instance, in the "enhancement effect/illusion"¹¹ the adapting stimulus is a wideband noise with a flat amplitude spectrum except in a narrow spectral region where there is a spectral notch (the flat-spectrum, wideband noise is filtered such that a narrow region of the spectrum is removed), and the test stimulus is the same wideband

noise presented with a flat-amplitude spectrum without the spectral notch (i.e., all spectral components within the bandpass of the noise are presented at the same average level). After a few minutes of exposure to the adapting stimulus with the spectral notch, a clear pitch corresponding to the region of the spectral notch is perceived as being present during the delivery of the following test stimulus, which has a flat amplitude spectrum. That is, the adapting exposure stimulus produced an illusory pitch in the test stimulus, since without such an adaptation process a flat-spectrum noise does not produce a pitch sensation, especially a sensation with a specific pitch.

Thus, one's perception of a particular sound can be significantly influenced by the acoustic context in which that sound occurs, especially when the contextual sounds have durations of seconds or minutes. Such effects of sound adaptation affect the auditory system's ability to process the sounds from the many possible sound sources in one's acoustic environment.

CHAPTER 22

SPEECH PRODUCTION AND SPEECH INTELLIGIBILITY

Christine H. Shadle
Haskins Laboratories
New Haven, Connecticut

1 INTRODUCTION

Production of speech involves a chain of processes: cognitive, motor, aerodynamic, and acoustic. Perception of speech is similarly complex. In this chapter we discuss the difference between our underlying knowledge of a language (the phonology) and the articulatory and acoustic realization of it (the phonetics). We then describe vocal tract anatomy in order to make clear the phonetic classification of speech sounds by manner, place, and voicing.

In the source-filter theory of speech production, the output of sound sources is filtered by the resonant properties of the vocal tract. We describe the main sound sources: laryngeal vibration, which generates an efficient quasi-periodic source, and noise sources. Means of describing the filtering properties of the vocal tract by use of circuit analogs, and the limitations thereof, are then covered. Finally, acoustic cues for the major manner classes are described as well as the ways in which speech perception can be influenced by background noise or transmission distortion. Differences between intelligibility and quality, and means of testing speech samples for each, are covered briefly.

2 PHONETIC CLASSIFICATION OF SPEECH SOUNDS

Speech can be thought of as consisting of a meaningful sequence of sounds. The meaning derives from the cognitive processes in both speaker and listener; the sound is produced by issuing motor commands to control the shape of the vocal tract and the amount of air passing through it. The sounds that make up speech are classified according to the articulatory characteristics of their production, which affect their acoustic characteristics. The contrasts between sounds that can signal differences in meaning and the ways in which they can be combined are governed by phonology, our deep understanding of a language's sound structure. The minimal sound units that affect meaning are called phonemes. However, the articulatory gestures for adjacent phonemes overlap and cause the acoustic characteristics to overlap also, a phenomenon called coarticulation. The actual sounds that result are called phones, and study of the speech as opposed to language characteristics is called phonetics.^{1,2}

Figure 1 shows a diagram of the lungs and vocal tract. Though the first use of these is for breathing, a person can deliberately control their lung pressure and the time-varying shape of their vocal tract in order to

produce a sound sequence recognizable as speech. The air pressure is controlled by six sets of muscles affecting lung volume: abdominal, diaphragm, and four sets of rib muscles. Air passes from the lungs through the trachea and glottis (the space between the vocal folds), the first possible location for significant sound generation. The air continues on up the pharynx; if the velum (soft palate) is down, it splits between oral and nasal cavities, allowing both cavities to resonate. The tongue is the most mobile and significant articulator, but the lower jaw, lips, and velum can all affect the vocal tract shape as well. Any variation in tract shape affects its resonances; if the vocal tract gets constricted enough anywhere along its length, sound generation results.

Speech sounds are generally classified according to how much the vocal tract is constricted (the *manner*), where along the tract the point of greatest constriction is (the *place*), and whether or not the vocal folds are vibrating (the *voicing*). The manner classes with the least constriction anywhere along the vocal tract include the *vowels*, *semivowels* (sounds like /j,w/ as in yell, wool), and *liquids* (most versions of r and l); for these the most constricted region may have a cross-sectional area of approximately 1.0 cm². The *nasals* have a complete constriction somewhere in the oral tract, and the velum is down; the place of a nasal depends on where in the oral tract the constriction is (at the lips for /m/, at the alveolar ridge just behind the teeth for /n/, or near the velum for /ŋ/, as in "sing"). For all of these manners the phonemes are voiced, meaning that a quasi-periodic sound is being produced by the vibration of the vocal folds.³

For the next three manners, in which the constriction is small enough that noise is generated along the tract, the phonemes may be voiced or voiceless. For *fricatives* a constriction is formed that is small enough (cross-sectional area from 0.03 to 0.20 cm²) for turbulence to be generated; the place of the constriction varies in English from lower lip and upper teeth for /f, v/, to the front part of the hard palate (just behind the alveolar ridge) for /ʃ, ʒ/, as in "shoo, azure"; /h/ is termed a glottal fricative, although the place at which the most turbulence noise is generated may not be at the glottis. Other places (e.g., pharynx, uvula; see Fig. 1) can be used to produce fricatives in other languages.⁴

For *stops*, the vocal tract is completely closed somewhere along its length, allowing pressure to build up. The constriction is then released, causing a brief burst of sound. There are six stops in English, listed

Figure 1 Diagram of the vocal tract. (Reprinted with permission from Flanagan,¹² p. 10.)

in voiceless–voiced pairs at three places: /p,b, t,d, k,g/, as in *Pooh, boo, too, do, coo, goo*. Additional sounds may be produced after the release, during the transition to the next phoneme. These are referred to by the mechanism thought to generate that part of the transitory noise: *frication*, while the area of the opening constriction is in the range of 0.03 to 0.20 cm², and then *aspiration*, thought to be produced by turbulence noise generated near the glottis. The aspiration phase typically only occurs for voiceless

stops during the time when the vocal folds are being adducted (brought together) for the following voiced sound; the glottis is small enough to generate turbulence noise, but too large still for phonation to occur.

Finally, *affricates* are intermediate between stops and fricatives. Initially there is complete closure as for a stop; the constriction is released more slowly than for a stop, however, producing a long interval of frication noise. In English there are only two affricates,

a voiceless–voiced pair with the same place: /tʃ, dʒ/ as in *Cheech* and *judge*.

3 ANATOMY, PHYSIOLOGY, AND SOUND PRODUCTION OF THE VOCAL FOLDS

Figure 2 shows a diagram of the vocal folds and surrounding structures. They consist of small muscles (the vocalis) with a cover of mucosal tissue. They are attached at the front to the inside of the thyroid cartilage (the Adam's apple), and at the back, to the arytenoid

cartilages, which sit on top of and can rotate with respect to the cricoid cartilage, which itself is hinged to the thyroid cartilage. Altogether, this means that there are many ways to control the vocal fold length and position with respect to each other. The tension on the folds results both from the distance between their endpoints (related to how the cartilages are positioned) and the degree to which the vocalis muscles are tensed. For the vocal folds to vibrate (also called *voicing*), the folds need to be positioned close to each other (to give a small glottal

Figure 2 Three views of the larynx and vocal folds: (a) posterior-lateral, (b) anterior-lateral, (c) superior view (transverse section at level of the vocal folds). (Reprinted with permission from Titze,⁵ p. 12.)

rest area), the folds must be tensioned above a threshold, and the transglottal pressure (the pressure drop across the glottis, i.e., from just below to just above the vocal folds) must be above a threshold. In the classic myoelastic theory, as the air flows through the glottis the Bernoulli force pulls the folds together. The muscle tension of the folds exerts a restoring force, and when these forces are balanced the folds begin to oscillate. When they are close enough together, the folds touch during the oscillation, closing the glottis mostly or completely. Air pressure then builds up until the folds are blown apart and the cycle resumes. More recent theories indicate that the Bernoulli force plays a role only during part of the cycle, and some form of asymmetry is needed for sound to be generated, as discussed by Titze.⁵ The closed phase of the cycle cuts the steady stream of air from the lungs into puffs, generating a periodic sound with a fundamental frequency (F0) that matches that of the mechanical oscillation, and a range of higher harmonics. The folds need not touch in order to generate a harmonic sound, however.⁵

The amount of energy in the harmonics and the subglottal pressure (the pressure below the glottis, at the upper end of the trachea) and volume velocities during voicing depend on the voice register being used. Voice registers exist in both speech and singing, though different terminology is used for each domain. Each register has a perceptibly different sound to it, which can be related to a different mode of vocal fold vibration caused by a different “setting” of laryngeal positioning and vocal fold tension. For instance, in modal voice (normal speaking voice) the entire muscle part of the vocal folds vibrates, and there is a significant closed phase that begins when the lower parts of the folds (nearest the trachea) slap together and ends when they peel apart from the bottom up. This results in a vertical wave traveling through the mass of the vocal fold and a complex vibration pattern that leads to the most energy in higher harmonics. In falsetto, the muscle mass is abducted (pulled apart) and only the mucosal cover vibrates, sometimes leading to incomplete closure along the length of the folds. This allows the vocal folds to vibrate at higher frequency, and there is noticeably less energy in the higher harmonics, as shown in Fig. 3.^{5,6}

The rest length and mass of the vocal folds, which are not under the control of the speaker, determine the fundamental frequency (F0) range; longer folds with more mass will tend to vibrate with lower F0. Typical vocal fold lengths are 17 to 24 mm for adult men and 13 to 17 mm for adult women.² The positioning and tension of the folds, and the subglottal pressure, determine the instantaneous F0 value within the range possible for the speaker and are under the speaker's control. In general, the entire F0 range is available for singing, but only the lower part of that range is used for speech. The average F0 in speaking is 125 Hz for adult men, 200 Hz for adult women, and 300 Hz or more for children, and yet adult women can range from 110 Hz (for altos) to 1400 Hz (for sopranos) and adult men from 30 to 900 Hz.⁵

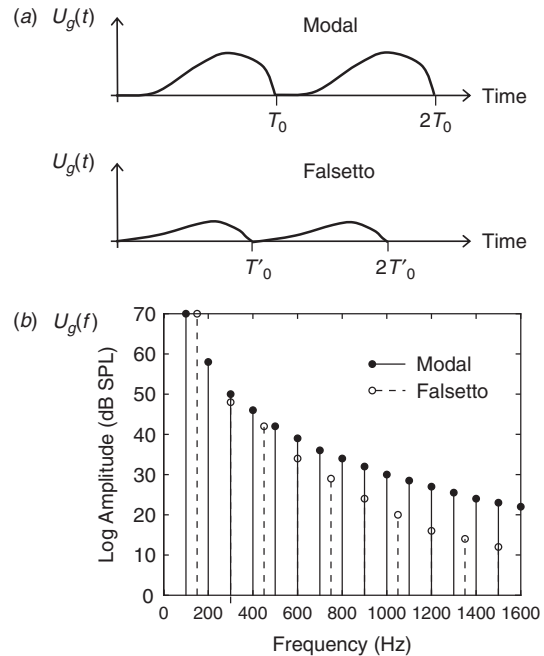

Figure 3 Graphs showing (a) idealized waveforms of volume velocity through the glottis and (b) corresponding source spectra for modal and falsetto voice qualities.

The subglottal pressure can range from 3 to 30 cm H₂O during voicing. Within a particular register the range may be smaller: For midvoice, subglottal pressure ranges from 10 to 30 cm H₂O, and the airflow rate is at least 60 cm³/s, whereas for falsetto, subglottal pressure ranges from 2 to 15 cm H₂O, and airflow is at least 70 cm³/s. For breathy voice, where the vocal folds might not contact each other at all though they are vibrating, airflow may be as high as 900 to 1000 cm³/s.³

4 NOISE SOURCES

During voiceless consonants the vocal folds are abducted (pulled apart), enlarging the glottis to an area ranging from 1.0 to 1.4 cm². Although this is smaller than the glottal area during breathing, it is significantly larger than the supraglottal constrictions for fricatives, which range from 0.03 to 0.2 cm². During the steady-state part of a fricative, the supraglottal constriction typically has a pressure drop across it of 6 to 8 cm H₂O and volume flow rate through it of 200 to 400 cm³/s. In the transitions into and out of the voiceless fricative, the glottis typically opens before the supraglottal constriction fully constricts, leading to higher volume velocities momentarily and giving the volume-velocity waveform a characteristic double-peaked profile. For /h/, with no significant supraglottal constriction, volume velocity can be as high as 1000 to 1200 cm³/s.⁷

For voiced fricatives, the vocal folds are abducted somewhat (pulled apart slightly) so that a slight peaking of the volume velocity can be observed in the transitions. In order to maintain voicing while still producing turbulence noise at the constriction, there must be pressure drops across both glottis and constriction.⁷ If either pressure drop ceases to be sufficient to maintain sound generation, a fricative either loses voicing (so that a particular token of a voiced fricative is referred to as *having devoiced*) or loses noise generation (as happens more often with the weak fricatives /v, ð/, as in *vee, the*). In voiced stops, during the closed phase the air continues to pass through the glottis, increasing the pressure in the oral cavity; this can decrease the transglottal pressure drop enough so that voicing ceases. However, the vocal folds maintain their adducted (pulled-together) position, so that as soon as the closure is released and the oral pressure drops, voicing restarts quickly. The time between closure release and voicing onset is known as the voice onset time (VOT); it differs significantly between voiced and voiceless stops (typically, from 0 to 30 ms and from 70 to 120 ms, respectively), and is one of the strong perceptual cues to the voicing of the stop.⁸

The Reynolds number is a dimensionless parameter that has been used in aerodynamics to scale systems with similar geometry. It is defined as $Re = VD/\nu$, where V and D are, respectively, a characteristic velocity and dimension of the system, and $\nu = 0.17 \text{ cm}^2/\text{s}$ is the kinematic viscosity of air. As Re increases, the flow changes from laminar to turbulent, often progressing through a transition region.⁹ For fricatives the constriction in the vocal tract is treated as an orifice in a pipe would be, and Re is defined using the mean velocity in the constriction for V and the constriction diameter for D . For synthesis one would then only need to determine the critical Reynolds number at which turbulence begins. However, one difficulty has been to determine the area of the constriction so that the characteristic velocity through it can be determined from the more easily measurable volume velocity. A few studies have shown that Re_{crit} ranges from 1700 to 2300 for speech; the relation of acoustic source strength to Re has been the subject of much research.^{7,8}

The acoustic output for speech varies over a wide range of amplitude and frequency, with vowels having a higher amplitude than voiceless consonants, especially at low frequencies. The long-term total root-mean-square (rms) speech sound pressure level for a male speaker using raised voice is, on average, 69 dB measured at 1 m directly in front of the speaker. Normal voice is about 6 dB less, loud voice about 6 dB more.

The long-term spectrum peaks at about 500 Hz for men, somewhat higher for women. The peak sounds range about 12 dB above the average level, and the minimum sounds about 18 dB below the average, as shown in Fig. 4.¹⁰

Figure 4 Graph of sound pressure spectrum level showing the regions corresponding to speech (of raised voice of a male speaker), the threshold of audibility for young ears, and the region of overload. (Reprinted with permission from Beranek,¹⁰ p. 408.)

5 SOURCE-FILTER THEORY OF SPEECH PRODUCTION

As a first approximation, the sound sources can be treated as independent of the filtering effects of the vocal tract. This, together with an assumption of plane-wave propagation in the tract, allows a circuit analogy to be used in which acoustic pressure is analogous to voltage and acoustic volume velocity to current. In the resulting transmission line analog, each section contains elements whose inductance, capacitance, or resistance depend on the cross-sectional area of the tract and the length of that section. Circuit theory can be used to derive the poles and zeros of the electrical system, which occur at the same frequencies as the acoustic resonances and antiresonances. Losses can be incorporated; the main source of loss is radiation at the lip opening, which can be modeled as an inductor and resistor in series.¹⁰ Other sources of loss include yielding walls (the vocal tract is lined with soft tissue except at the hard palate and teeth), and viscosity and heat conduction; these are modeled with extra elements within each section of the transmission line. The transmission line can be converted to digital form, as a digital delay line.^{8,11}

Because the tongue and other articulators move slowly relative to the vocal folds, the vocal tract filter can be treated as static during a single pitch period (vocal fold cycle). The vocal tract transfer function is defined to be the ratio of the “output,” typically the volume velocity at the lips, to the “input,” the source characteristic. Its poles are always the natural resonances of the entire system; its zeros depend on the topology of the system. If the source is at one end, the output is at the other end, and there are no parallel branches, there are no zeros; this is the case for nonnasalized vowels, as shown in Fig. 5a. If the source is intermediate (i.e., a supraglottal source, as for noise-excited consonants), there will be zeros corresponding to the resonances of the back cavities, which may destructively interfere with the system resonances (see Fig. 5b). Likewise, if the tract has any side branches, as, for instance, in nasals, there will be zeros corresponding to the resonances of the side branch (see Fig. 5c).⁸

Within these general characteristics, the vocal tract shape and especially the place of greatest constriction determine the frequencies of each resonance and antiresonance. Vowels can be distinguished by the first two resonances; the first three resonances distinguish liquids (/l and r/) also. Figure 6 shows idealized transfer functions for two vowels, the fricative “sh,” and

Figure 5 Block diagrams of source-filter model of speech production for (a) vowel, (b) fricative or stop, and (c) nasal. The glottal voicing source is indicated by a volume-velocity source analogous to a current source, U_g . The noise source is indicated by a pressure source analogous to a voltage source, p_s .

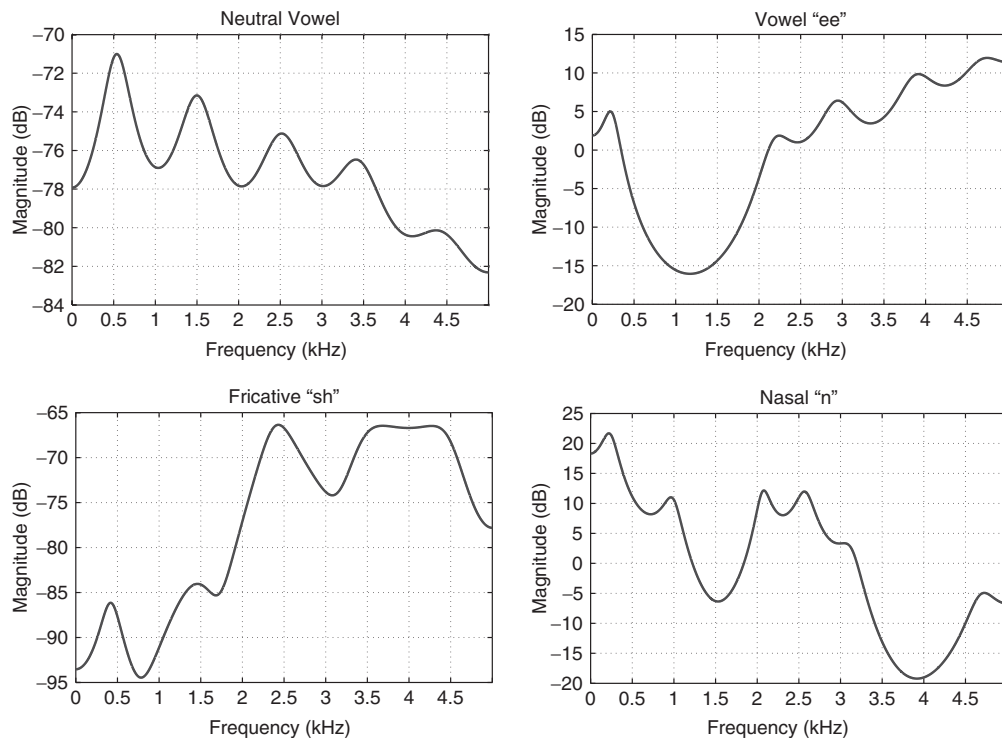

Figure 6 Typical transfer functions (U_L/U_g , U_L/p_s , or U_n/U_g) for the major classes of speech sounds. (Top) Vowels—neutral vowel schwa (as in “the”) and /i/ (as in “he”). (Lower left) The fricative “sh.” (Lower right) The nasal /n/.

the nasal /n/. The vowels have all-pole transfer functions, with the pole frequency differing according to the vocal tract shape. The fricative and nasal transfer functions have zeros as well as poles determined by the source location and oral cavity length, respectively. The transfer function for a stop is fricative-like immediately after release, becoming vowel-like (though noise excited) in the aspiration phase.

Two classic source models that work well and so continue to be used in synthesizers are the two-mass model of vocal fold vibration and a series pressure source located in the vicinity of the most constricted region for turbulence noise sources.¹² The former models each vocal fold as a combination of two masses and three springs, allowing mass, tension, and coupling to be set, as well as glottal rest area. The input parameter is subglottal pressure; it outputs volume velocity. Other models have been developed, including 16-mass models, ribbon and beam models, and finite element models of each vocal fold.⁵ There have also been studies showing that there is interaction of the vocal fold vibration with the vocal tract acoustic impedance, and studies of the aeroacoustic effects of the vocal fold vibration.

Noise sources have long been modeled as acoustic pressure sources, analogous to voltage sources, placed in series. The location of such a source in the tract model affects the frequencies of the antiresonances (and thus the zeros of the transfer function) significantly. The overall source strength and how it changes in time, and the spectral characteristic of the source, also affect the predicted radiated sound. Some solutions used in synthesis include placement of the source according to the phoneme being synthesized,¹³ or at a set distance downstream of a constriction¹²; in Flanagan and Cherry's noise source model the source strength is controlled by the Reynolds number of the upstream constriction, and the spectral characteristic consists of high-pass-filtered white noise (pp. 253–259 in Ref. 12). More recent results indicate that all aspects of turbulence noise generation—spatial and temporal distribution and spectral characteristics—depend strongly on the geometry of the tract downstream of the constriction, which is not fully specified in a model based on the cross-sectional areas along the tract.⁷ Models that differ for each phoneme offer some improvement,⁸ but any source generated by or pasted into a circuit analog will never accurately represent flow noise sources.

6 ENGINEERING ASPECTS OF SPEECH PERCEPTION

Speech perception encompasses the subset of auditory perception that allows us to understand speech and simultaneously deduce background acoustic characteristics and the speaker's age, gender, dialect, and mood. Some aspects of speech perception are innate; others are learned as part of learning a language. Various speech technologies attempt to replicate some part of human speech perception, exploiting current knowledge to do so. Thus, speech transmission and coding

seek to capture only the parts of the speech signal that are most vital for communication; speech recognition aims to produce written text from a speech signal, ignoring or neutralizing information about the speaker; speaker identification and verification ignore the segmental information but seek to correctly identify the speaker, or verify that the speaker's acoustic characteristics match their other characteristics such as an identity card presented to the computer.

Different speech sounds are distinguished from each other by differing sets of acoustic cues. For vowels, the frequencies of the lowest two or three resonances are most important, sufficient to deserve another name: The resonances are referred to as *formants* and numbered from lowest frequency on up. The first three vowel formants range between 200 and 3000 Hz for adults. The most sensitive part of our hearing is from 500 to 5000 Hz. The telephone capitalizes on these facts, having a bandwidth of 300 to 3400 Hz. This means that the fundamental frequency F_0 is usually filtered out before transmission over the telephone; our auditory systems are able to deduce it from the harmonics that are transmitted.¹¹ Studies have been done to try to establish the bandwidth holding the “essential information” of speech. But intelligibility degrades only slightly when a large part of the spectrum is filtered out: For instance, low-pass filtering at 1800 Hz results in approximately 65% intelligibility (meaning that 65% of the phonemes could be correctly transcribed on average), but high-pass filtering at 1800 Hz yields about the same intelligibility. Clearly, there is a lot of redundancy in speech signals.¹⁴ Mobile phones exploit more subtle aspects of auditory perception such as masking in order to compress the signal, thus minimizing the bandwidth needed for transmission.

In order to measure the success of such compression algorithms, and also to evaluate speech synthesizers, a variety of objective and subjective measures have arisen. A distinction must be made between speech intelligibility and quality. Simply stated, intelligibility measures the likelihood that the speech will be understood; speech quality measures naturalness and ease of listening. These concepts are equally valid for considering human speech with background noise, human speech that has been distorted or degraded by its method of recording or transmission, and computer-synthesized speech.¹¹ Both dimensions are important because it is possible to improve the speech quality and yet worsen its intelligibility, and vice versa; speech enhancement algorithms usually aim to improve both dimensions.

Normally, speech needs to be approximately 6 dB higher in level than background noise to be intelligible,¹⁴ so many enhancement algorithms focus on improving the signal-to-noise ratio (SNR). However, SNR is a poor guide to the perceptual effects of a particular kind of noise. Also, it is well known that speakers will speak differently in the presence of background noise, changing duration, intensity, spectral tilt, among other parameters; these effects are not easily corrected for.^{15,16} Consonants affect intelligibility of speech more than vowels and tend also

to have distinguishing acoustic cues that are noisy themselves and range over higher frequencies. An early study investigated consonant confusion patterns that occurred at different levels of background noise and with different filters applied; the weak fricatives were most readily confused.¹⁷ More recently, the Diagnostic Rhyme Test (DRT)¹⁸ was devised so that intelligibility could be tested feature by feature, for six features such as nasality, voicing, sonorance, and so on. The effect of a particular kind of distortion or background noise can be delineated. Speech quality can similarly be quantified using the Diagnostic Acceptability Measure (DAM).^{18–20} These DRT and DAM measures, based on formal listening tests using human subjects, are termed subjective tests; many objective tests that do not use human subjects have been developed, in particular to evaluate mobile phone compression and coding algorithms.²¹

PART IV

EFFECTS OF NOISE, BLAST, VIBRATION, AND SHOCK ON PEOPLE

CHAPTER 23

GENERAL INTRODUCTION TO NOISE AND VIBRATION EFFECTS ON PEOPLE AND HEARING CONSERVATION

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

Noise and vibration may have undesirable effects on people. At low sound pressure levels, noise may cause annoyance and sleep disturbance. At increased levels, noise begins to interfere with speech and other forms of communication; at still higher levels that are sustained over a long period of time in industrial and other occupational environments, noise can cause permanent hearing damage. Loud impulsive and impact noise are known to cause immediate hearing damage. Similarly, whole-body vibration experienced at low levels may cause discomfort, while such vibration at higher levels can be responsible for a variety of effects including reduced cognitive performance and interference with visual tasks and manual control. Undesirable vibration may be experienced in vehicles and in buildings and can be caused by road forces, unbalanced machinery forces, turbulent boundary layer pressure fluctuations, and wind forces. High levels of sustained vibration experienced by operators of hand-held machines can cause problems with circulation and neuropathy of the peripheral nerves and can result in chronic diseases of the hand and arm. This introductory chapter summarizes some of the main effects of noise and vibration on people. For more in-depth discussion, the reader should consult the chapters following in Part IV of this book.

2 SLEEP DISTURBANCE

It is well known that noise can interfere with sleep. Not only is the level of the noise important for sleep interference to occur, but so is its spectral content, number and frequency of occurrences, and other factor. Even very quiet sounds such as dripping taps, ticking of clocks, and snoring of a spouse can disturb sleep. One's own whispered name can elicit awakening as reliably as sounds 30 or 40 dB higher in level. Common sources of noise in the community that will interfere with sleep are comprised of all forms of transportation, including road and rail traffic, aircraft, construction, and light or heavy industry. Some airports restrict night time aircraft movements. Road traffic is normally reduced at night and is less disturbing but is still potentially a problem. Noise interferes with sleep in two main ways: (1) it can result in more disturbed, lower quality sleep, and (2) it

can awaken the sleeper. Unfortunately, although there has been a considerable amount of research into sleep interference caused by noise, there is no internationally accepted way of evaluating the sleep interference that it causes or indeed of the best techniques to adopt in carrying out research into the effects of noise on sleep. Also, little is known about the cumulative long-term effects of sleep disturbance or sleep deprivation caused by noise. Fortunately, despite the lack of in-depth knowledge, sufficient noise-induced sleep interference data are available to provide general guidance for land-use planning, environmental impact statements for new highways and airports, and sound insulation programs for housing. Chapter 24 provides an overview of knowledge about sleep disturbance caused by noise.

3 ANNOYANCE

Noise consists of sounds that people do not enjoy and do not want to hear. However, it is difficult to relate the annoyance caused by noise to purely acoustical phenomena or descriptors. When people are forced to listen to noise against their will, they may find it annoying, and certainly if the sound pressure level of the noise increases as they are listening, their annoyance will likely increase. Louder sounds are usually more annoying, but the annoyance caused by a noise is not determined solely by its loudness. Very short bursts of noise are usually judged to be not as loud as longer bursts at the same sound pressure level. The loudness increases as the burst duration is increased until it reaches about $\frac{1}{8}$ to $\frac{1}{4}$ s, after which the loudness reaches an asymptotic value, and the duration of the noise at that level does not affect its judged loudness. On the other hand, the annoyance of a noise at a constant sound pressure level may continue growing well beyond the $\frac{1}{4}$ s burst duration as the noise disturbance continues.

Annoyance caused by noise also depends on several other factors apart from the acoustical aspects, which include its spectral content, tonal content, cyclic or repetitive nature, frequency of occurrence, and time of day. Nonacoustical factors include biological and sociological factors and such factors as previous experience and perceived malfeasance. We are all aware of the annoyance caused by noise that we cannot easily control, such as that caused by barking dogs, dripping taps, humming of fluorescent lights, and the

like. The fact that the listener does not benefit from the noise, cannot stop the noise, and/or control it is important. For instance, the noise made by one's own automobile may not be judged very annoying while the noise made by other peoples' vehicles, motorcycles, lawnmowers, and aircraft operations at a nearby airport, even if experienced at lower sound pressure levels, may be judged much more disturbing and annoying. Chapter 25 reviews the annoyance of noise in detail and provides references for further reading.

4 INFRA-SOUND, LOW-FREQUENCY NOISE, AND ULTRASOUND

So far we have described the disturbing effects that are produced by noise within the frequency range of human hearing from about 20 to 16,000 Hz. But noise above and below this frequency range can also cause disturbance to people. Very low frequency noise or *infrasound* (usually considered to be at frequencies below 20 Hz) may be very intense although "inaudible" in the traditional sense of hearing; but nevertheless it may cause a sensation of pressure or presence in the ears. Low-frequency noise (LFN) between about 20 and 100 Hz, which is within the normally audible range, is usually more disturbing than infrasound. Low-frequency noise in the region of 20 to 50 Hz seems to be the worst problem and more disturbing than infrasound. Sources of infrasound and LFN noise include (1) air-conditioning systems in buildings with variable air volume controls or with large-diameter slow-speed fans and blowers and long ductwork in which low-frequency standing waves can be excited, (2) oil and gas burners, (3) boilers, and (4) diesel locomotives and truck and car cabins. Ultrasound covering the range 16,000 to 40,000 Hz is generated in many industrial and commercial devices and processes.

Chapter 26 reviews the known effects of infrasound, LFN, and ultrasound in more detail. Currently, our best information is that infra- and ultrasound can be tolerated at high sound pressure levels up to 140 dB for very short exposure times, while at levels between 110 and 130 dB, infra- and ultrasound can be tolerated for periods as long as 24 hours without apparent permanent physiological or psychological effects. There is no current evidence that levels of infrasound, LF, or ultrasound lower than 90 to 110 dB lead to permanent physiological or psychological damage or other side effects.

5 IMPULSIVE AND IMPACT NOISE

High levels of impulsive and impact noise pose special threats to human hearing. These types of noise can also be very annoying. It is well known now that high levels of such noise damage the cochlea and its hair cells through mechanical processes. Unfortunately, there is currently no commonly accepted definition or recognized standard for what constitutes impulsive noise. Impulsive noise damage cannot be simply related to knowledge of the peak sound pressure level. The duration, number of impulsive events, impulse

waveform, and initial rise time are also all important in predicting whether impulsive or impact noise is likely to result in immediate hearing damage. Impulse noise damage also does not seem to correlate with the noise energy absorbed by the ear. It is known that hearing damage caused by a combination of impulsive noise events during steady background noise cannot be judged by simply adding the noise energy contained in each and may indeed be greater than simple addition would suggest.

There is a huge variation in the characteristics of impulsive and impact noise to which people may be exposed. Peak sound pressure levels can be from 100 dB to as much as 185 dB, and impulse durations may vary from as little as a few microseconds to as much as hundreds of milliseconds. Impulses can be comprised of single events or multiple or repeated events. Cole has classified impulse and impact noise into two main types: (1) single nonreverberant impulses (termed A waves) and (2) reverberant impact noise (termed B waves) (see Chapter 27).

Explosions and the blast waves they create (often commonly called Friedlander waves) can be classified as A waves in Cole's system. They can have peak sound pressure levels of over 150 dB. They are really shock waves and are not purely sound waves. Riveting and punch press and forge forming and other machining processes in industry can result in reverberant noise caused by ringing of the manufactured parts. Such ringing noise is classified as B waves in this system. Although Cole's system includes the effects of peak sound pressure level, duration, and number of impulsive events, it is not completely comprehensive since it neglects the rise times, spectral contents, and temporal patterns of the impulses. Bruel has shown that crest factors as high as 50 dB are common in impulsive noises (see Chapter 27). Unfortunately, there is still no real consensus on how to predict and treat the damaging effects of impulsive noise compared to continuous intense noise. Chapter 27 discusses impulsive and impact noises in more detail.

6 INTENSE NOISE AND HEARING LOSS

Continuous intense noise at much lower sound pressure levels than discussed in Section 5 can also produce hearing loss. The level needed to produce the hearing loss is much lower than the peak impulsive noise levels required to produce immediate damage. Protective mechanisms exist in the middle ear, which reduce the damaging effect of continuous intense noise. These mechanisms, however, only reduce the noise levels received by the cochlea by about 5 dB and are insufficient to protect the cochlea against most continuous intense noise. The hearing loss caused by continuous intense noise is described in detail in Chapter 28.

Hearing loss can be classified into two main types and is normally measured in terms of the shift of the following hearing threshold shifts (see Chapter 28): (1) Temporary threshold shift (TTS) is the shift in hearing threshold caused by noise that returns to normal after periods of 24 to

(a)

(b)

Figure 1 Electron microscope image of the hair cells in the cochlea (a) hair cells before noise exposure and (b) damaged hair cells after intense noise exposure. (Courtesy of Pierre Campo, INRS, Departement PS, Vandoeuvre, France.)

48 hours. (2) Permanent threshold shift (PTS) is the shift in hearing threshold that is nonrecoverable even after extended periods of rest. PTS caused by exposure to intense noise over extended periods produces permanent irrecoverable damage to the cochlea. Figure 1 shows the destruction of the hair cells in a cochlea of a rat caused by intense noise.

Some people have hearing mechanisms that are more sensitive than other people's and are more prone to damage from continuous intense noise and to suffer PTS. Because harmful noise can be quite different in frequency content, often A-weighted sound pressure level is used as a measure of the intense noise for the prediction of hearing impairment (PTS). Continuous A-weighted sound pressure levels above 75 dB can produce hearing loss in people with the most sensitive hearing if experienced for extended periods of some years. As the A-weighted level increases,

an increasing fraction of the workforce experiences PTS. The PTS expected at different levels has been predicted by several organizations including the International Organization for Standardization (ISO), the Occupational Safety and Health Administration (OSHA), and the National Institute for Occupational Safety and Health (NIOSH) (see Table 1).

Some countries have hearing regulations that restrict the amount of daily noise exposure a person should be allowed to experience at different A-weighted sound pressure levels. Most countries use the 3-dB trading ratio (also known as the exchange rate) as the A-weighted level is changed. This assumes a linear relationship between noise energy absorbed and hearing loss. If the level increases by 3 dB it is assumed that the noise dose will be the same for an exposure period of half the time. In the United States, a 5-dB trading ratio (also known as the exchange rate) is used before the allowable exposure time is halved, which assumes that a worker get some breaks from the intense noise during the day's noise. Table 2 shows the time-weighted average (TWA) noise level limits promulgated by OSHA.

7 EFFECTS OF VIBRATION ON PEOPLE

Vibration has unwanted effects on people.² People are also very sensitive to vibration.

Undesired vibration can be experienced in vehicles, aircraft, buildings, and other locations. Vibration is normally measured in terms of acceleration levels. With low vibration levels, people may experience discomfort such as motion sickness. The amount of discomfort depends not only upon the magnitude but on the frequency of vibration and its direction and

Table 1 Estimated Excess Risk of Incurring Material Hearing Impairment^a as a Function of Average Daily Noise Exposure over a 40-year Working Lifetime^b

Reporting Organization	Average Daily A-weighted Noise Level Exposure (dB)	Excess Risk (%) ^c

^a No exposure to continuous or intermittent A-weighted sound pressure level in excess of 115 dB.

^b Exposure to impulsive or impact noise should not exceed a peak sound pressure level of 140 dB.

^c No exposure to continuous, intermittent, or impact noise in excess of a C-weighted peak sound pressure level of 140 dB.

duration as well. As vibration levels increase, cognitive performance can be affected, and interference with visual tasks and manual control can occur. Vibration can be classified as whole body or part of the body such as an organ or limb. High levels of sustained vibration over an extended period of time can cause neuromuscular damage for hand-held machine operators and vascular and articular disorders. See Chapter 29 for more detailed discussion of this topic.

8 EFFECTS OF MECHANICAL SHOCK

Vibration caused by suddenly applied forces is normally classified as a shock.² With a shock, the maximum force is usually experienced in a few tenths of a second, and the duration of the applied forces is normally less than one second. Shocks can cause discomfort, but if of great enough magnitude, they can cause injury and if of sufficient magnitude, death. Like vibration, the effect of shocks upon people depends upon several factors including their magnitude, direction, frequency content, and whether or not impacts occur in conjunction with the shocks. Survivability of intense shocks and impacts depends to a large extent on whether or not the human body is restrained. Both experimental and theoretical models of human shock phenomena are used to study the effects of shock. Chapter 30 discusses the effects of mechanical shock and impact on people in detail.

9 HEARING PROTECTORS

It is best practice to reduce noise through: (1) the use of passive engineering controls such as use of enclosures, sound-absorbing materials, barriers, vibration isolators, etc., and then (2) using administrative measures such as restricting the exposure of personnel by limiting duration, proximity to noise sources, and the like. In cases where it is not practical or economical to reduce noise exposure to sound pressure levels that cause hearing hazards or annoyance, then hearing protectors should

be used.¹ Hearing protector devices (HPDs) can give noise protection of the order of 30 to 40 dB, depending on frequency, if used properly. Unfortunately, if they are incorrectly or improperly fitted, then the attenuation they can provide is significantly reduced. There are four main types of HPDs: earplugs, earmuffs, semi inserts, and helmets. Earplugs are generally low-cost, self-expanding types that are inserted in the ear canal and must be fitted correctly to achieve the benefit. Custom-molded earplugs can be made to fit an individual's ear canals precisely. Some people find earplugs uncomfortable to wear and prefer earmuffs.

Earmuffs use a seal around the pinna to protect it and a cup usually containing sound absorbing material to isolate the ear further from the environment. If fitted properly, earmuffs can be very effective. Unfortunately, earmuffs can be difficult to seal properly. Hair and glasses can break the seals to the head causing leaks and resulting in a severe degradation of the acoustical attenuation they can provide. In addition they have the disadvantage that they can become uncomfortable to wear in hot weather. The use of earmuffs simultaneously with earplugs can provide some small additional noise attenuation, but not as much as the two individual HPD attenuations added in decibels. Semi inserts consist of earplugs held in place in the ear canals under pressure provided by a metal or plastic band. These are convenient to wear but also have the tendency to provide imperfect sealing of the ear canal. If the plug portion does not extend into the ear canal properly, the semi insert HPD provide little hearing protection and can give the user a false sense of security.

Helmets usually incorporate semi inserts and in principle can provide slightly greater noise attenuation than the other HPD types. Attenuation is provided not only for noise traveling to the middle and inner ear through the ear canal, but for noise reaching the hearing organ through skull bone conduction. Helmets also provide some crash and impact protection to the head in addition to noise attenuation and are often used in conditions that are hazardous not only for noise but potential head injury from other threats. Unfortunately, the hearing protection they provide is also reduced if the semi inserts are improperly sealed in the ear canals. Chapter 31 contains more detailed discussion on hearing protectors.

10 NUMBERS OF PEOPLE EXPOSED

Large numbers of workers involved in manufacturing, utilities, transportation, construction, agriculture, and mining work in noisy conditions, which present hazards to hearing. In 1981, OSHA estimated that 7.9 million people in the United States working in manufacturing were exposed occupationally, to daily A-weighted sound pressure levels at or above 80 dB. In the same year, the U.S. Environment Protection Agency (EPA) estimated that more than 9 million U.S. workers were exposed occupationally to daily A-weighted levels above 85 dB. More than half of these workers were involved in manufacturing and utilities. Chapter 32 gives estimates for the number

of people working in hazardous noise conditions in other countries as well as the United States. Many governments require or mandate hearing conservation programs for workers in industries and in other occupations in which hazardous noise conditions exist. These are described in Chapter 33.

11 HEARING CONSERVATION PROGRAMS

Hearing conservation programs are designed to protect workers from the effects of hazardous noise environments. Protection can be provided not only by use of engineering controls designed to reduce the emission of noise sources, control of noise and vibration paths, and the provision of HPDs, but by the limitation of personnel exposure to noise as well. For instance, arranging for a machine to be monitored with a control panel that is located at some distance from a machine, instead of right next to it, can reduce personnel noise exposure. The rotation of personnel between locations with different noise levels during a workday can ensure that one person does not stay in the same high noise level throughout the workday. Chapter 33 describes hearing conservation programs and, in addition, some legal issues including torts, liabilities, and occupational injury compensation.

12 NOISE AND VIBRATION CRITERIA

Various noise and vibration environments have produced the requirements for different criteria to reduce

annoyance, discomfort, speech and sleep interference, and to reduce their hazardous effects. This has resulted in different rating measures being devised to account for these effects. For instance, it has been found impossible to use one noise measure to account for the effects of noise on speech interference, sleep interference, and air-conditioning noise in buildings, although sometimes the A-weighted 8-h equivalent sound pressure level is used. This measure, however, is obviously not suitable for hazardous impact noise and to assess the impact of time-varying noise such as aircraft movements at airports. The main reason is that this measure does not allow for variations in level and for night versus daytime exposure and the need to have a lower noise environment at night. Chapter 34 reviews the most common noise and vibration level criteria and rating measures in use in 2007.

1 INTRODUCTION

Sleep disturbance is a common effect of exposure to community noise, especially for transportation noise, such as that from aircraft, road traffic, and railways. Protection of sleep is necessary for a good quality of life,^{1,2} as daytime well-being often depends on the previous night's sleep quality and efficiency. Sleep disturbance research has produced a considerable variability of results and little concrete guidance on how to assess potential sleep disturbance in a community. The absence of one internationally accepted exposure–effect (or dose–response) relationship is largely due to the lack of one “best choice” research technique, as well as the complex interactions of the many factors that influence sleep disturbance. Little is known about the *long-term, cumulative effects* of intermittent sleep disturbance from community noise exposures and only a handful of large-scale field studies have been conducted over the past decade. In spite of these limitations, current scientific data on noise-induced sleep disturbance can be used to support transportation-related environmental noise impact analyses, land-use planning, housing sound insulation programs, and related environmental noise management activities. This chapter provides information on noise exposure metrics, human response measures, dose–response curves, and recommended noise exposure criteria for predicting and assessing sleep disturbance at the community level.

2 WHY IS PREDICTION OF SLEEP DISTURBANCE IMPORTANT?

Most community development, such as a new highway or a new commuter rail line, projects result in an increase in community noise. The environmental impact analysis process and related environmental noise management activities should involve the prediction of future sleep disturbances due to the

expected increase in noise levels when increased nighttime noise exposures are expected. When a community development project involves nighttime noise exposure, it is important to consider the major impacts expected, including both sleep disturbance and community annoyance.

3 NOISE EXPOSURE – DIFFERENT METRICS AND NOISE CHARACTERISTICS

The sleep disturbance field study database described below consists largely of data from aircraft noise studies, although there are some data points from studies of road and rail traffic. This limitation should be considered when predicting sleep disturbance from the latter two sources. Different indices have been used to describe various community noise exposures, and there is no general agreement on which should be preferred among the many various available noise indices. The choice of noise metrics for establishing exposure criteria depends on both the particular type of noise source and the particular effect being studied. Even for sleep disturbance due to transportation noise exposure, there is no single noise exposure metric or measurement approach that is generally agreed upon. One important review of the sleep disturbance literature by Pearsons et al.³ showed that, overall, sound exposure level (SEL) was a better predictor of sleep disturbance across the various studies included in their metaanalysis than was the maximum frequency–weight sound pressure level (L_{AFmax}). However, other reviews of the literature showed that measures of peak sound pressure level are better predictors of disturbances during sleep than measures of average sound pressure level.⁴ The community noise guidelines recently published by the World Health Organization (WHO¹) allow the use of either L_{AFmax} or SEL. Thus, there is still no consensus on the best metric to use.

4 SLEEP DISTURBANCE

4.1 How to Assess Sleep Disturbance — Objective Evaluation of Sleep Disturbance

A variety of different techniques have historically been used in sleep disturbance research. Some studies are conducted in research laboratories using simulated noise exposures,^{5,6} while other studies are conducted in “field settings”—that is, in people’s own homes—using actual community noises. The effects of noise on sleep can be measured immediately or evaluated afterwards—at the end of the night or during the following day. Immediate effects are mainly measured by objective data recorded during sleep, and they show how the sleeper is reacting to noise, either in terms of changes in sleep stage architecture or behaviorally indicated awakenings. Sleep stage architecture measurements include the following:

Sleep Architecture The stage and cycle infrastructure of rapid eye movement (REM) and non-REM sleep, as these relate to each other for the individual.

Sleep Structure Similar to sleep architecture. However, sleep structure—in addition to encompassing sleep stage and cycle relationships—assesses the within-stage qualities of the electroencephalogram (EEG) and other physiological attributes.

Aftereffects are measured in the morning by subjective evaluations of sleep quality or by objective biochemical data (such as levels of stress hormones, including adrenalin, noradrenalin, and cortisol)^{7–9} or by performance levels during the following day.^{10,11}

Because of the differences in research techniques used in sleep disturbance studies, it is not surprising that the results of various studies are quite different from each other, especially conclusions about the number of sleep stage changes and awakenings. Many published field studies present limited noise exposure data and limited sleep disturbance indices, mainly because the choice of measurement methods and sleep disturbance indicators are still controversial. This is particularly the case for studies using either behavioral awakening, as indicated by pushing a button when awakened,¹² and/or body motility (i.e., body movement as measured by an actimeter) as indicators of nocturnal awakening.^{13,14} However, changes in sleep architecture, including both sleep stage changes and short-lasting awakenings as determined by EEG recordings, are more subtle and would often be totally missed by both the button-press and the actimetry research techniques. In addition, EEG recordings provide considerable data on a variety of sleep-related parameters. This technique is most useful for new research to increase our knowledge about the basic mechanisms of sleep.

Electroencephalographic studies provide the most detailed information about changes in sleep architecture in response to intruding noises and involve well-established research techniques for improving our understanding of the mechanisms of sleep, but the

long-term effects of the observed EEG responses are not known. Thus, it is difficult to determine practical noise exposure criteria using these data. Although physiological indicators of awakening would ideally provide the best data, usable conclusions from research using EEG and other physiological parameters, especially data from field research studies, are not yet ready for use in establishing noise exposure policies. Thus, guidelines for nighttime noise exposure are presently based on behavioral measures, either awakenings or bodily movements.

Each measurement approach has its own advantages and disadvantages. Behavioral awakening studies provide a clear and unambiguous indicator of awakening. However, there could be human responses to nighttime noise intrusions that do not result in sufficient awakening for the person to push the test button. Body motility studies provide a considerable amount of data on bodily movements that could indicate a stress response, but there is no way to determine whether or not a person was awakened by the noise, which would be a more clear indicator of an effect. In addition, body movements during sleep are quite normal physiological events. Only a small amount of them result in behavioral awakenings and only some of these could be attributed to noise; most nighttime body movements do not result in awakening.¹⁴ Therefore, measuring bodily movement by actimetric techniques during sleep has limitations as a technique for predicting awakenings. However, it is a valuable research technique that can be used in people’s homes and is relatively inexpensive. The EEG recording technique provides some of the most detailed and useful information about sleep disturbance, but the results of EEG studies in the laboratory need real-world confirmation and validation in field studies, which are very expensive and quite difficult to perform.

5 IMMEDIATE EFFECTS

The following list includes some of the various objective physiological, biochemical, and behavioral measures used to assess the immediate effects of nighttime noise:

- Electroencephalograph arousal responses
- Sleep stage changes
- Nocturnal awakenings
- Total waking time
- Autonomic responses

6 AFTEREFFECT MEASURES

Chronic partial sleep deprivation induces marked tiredness, increases a low vigilance state, and reduces both daytime performance and the overall quality of life.^{1,15} Other measures made after nighttime noise exposure include a variety of daytime task performance tests and tests of cognitive functioning, and the excretion of stress hormones in the morning urine flow can be measured by researchers to evaluate the impact

of overall noise exposure at night.^{16,17} However, all of these types of measurements are quite difficult to perform in field situations and only a few studies have included them in recent years.

7 HEALTH EFFECTS

The goal of the scientific community is to be able to link sleep disturbance from noise exposure with long-term health impacts. Of particular interest is the possible relationship between noise and the stress responses it produces. These stress responses have the potential to be linked to hypertension, cardiovascular disease, and other severe medical problems.^{18–26} However, it is difficult to separate out the effects of just the noise exposure because undisturbed sleep, as a prerequisite to good health, requires an environment with all of the following:

- Adequate noise environment
- Clean room air
- Adequate room temperature
- Adequate atmospheric humidity
- Adequate darkness

Thus, protection of sleep in community populations requires a broader health perspective. The combination of many different types of community noise sources, in conjunction with many nonnoise environmental factors, can have a significant impact on sleep quality and overall health. There is also a need to protect sensitive groups and shift workers who sleep during the day.²⁷

8 SUBJECTIVE EVALUATION OF SLEEP DISTURBANCE

Recordings of objective sleep disturbance data can be too costly and too difficult to use with large samples of the population or when research funding is scarce, while subjective evaluation of sleep quality using a morning-after questionnaire is an easier and less costly way of collecting field data. Sleep disturbance can be assessed from complaints about bad sleep quality, nocturnal awakenings, often accompanied by impaired quality of the subsequent daytime period with increased tiredness, daytime sleepiness, and need for compensatory resting periods. However, the use of subjective complaints is quite different than an assessment based on objective (instrumental) measures. There are many factors that influence people's subjective evaluations of their own sleep quality. It has been very difficult for researchers to find a clear relationship between subjective complaints and actual noise exposure levels. In general, however, subjective self-reports of awakenings do not correlate well with more objective measures of sleep disturbance.^{28–30} In the Netherlands Organization for Applied Scientific Research (TNO) analysis by Passchier-Vermeer, et al.,²⁹ no relationship could be established between a measure of the total night's exposure, the nighttime, 8-h, equivalent continuous A-weighted sound pressure

level ($L_{Aeq,8h}$) (defined as L_{night}) and self-reported sleep disturbance on the basis of the analysis of aircraft noise surveys. Thus, future use of self-reports of movement, awakenings, or other sleep-related effects, needs serious reconsideration because of the questionable validity of self-report data for predicting actual responses to noise events.

9 LABORATORY VERSUS IN-HOME FIELD STUDIES

Survey of the literature shows large differences between results obtained in numerous laboratory studies and those issued from epidemiological or experimental studies made in real in-home situations. In the Pearsons et al.³ metaanalysis, a comprehensive database representing over 25 years of both laboratory and field research on noise-induced sleep disturbance was compiled and analyzed. Those researchers firmly established the rather large differences observed between laboratory and in-home field studies, with nocturnal awakenings being much greater in laboratory studies. It would certainly be the case that a certain degree of habituation occurs in people's own homes for the number of noise-induced awakenings they experience. On the other hand, modifications in sleep stage architecture, especially the relationships between the time spent in the various sleep stages, show little habituation with time, while purely autonomic responses, such as heart rate, breathing rate, and systolic blood pressure, do not habituate at all over extended periods of time.^{31–34}

10 CURRENT EXPOSURE-RESPONSE RELATIONSHIPS FOR SLEEP DISTURBANCE

10.1 Position of the European Commission

In July 2002 the European Commission (EC) published the "EU Directive on the Assessment and Management of Environmental Noise" (END).³⁵ This document specifies L_{night} as the indicator for sleep disturbance, although a response measure for sleep disturbance has not yet been selected. As part of developing the END, the European Commission contracted with TNO to derive exposure-response relationships between L_{night} and sleep disturbance for transportation noise, which will be included in a future Annex to the END and will most likely use motility (i.e., body movements) as the response (more information on the proposed EC approach can be found in Passchier-Vermeer et al.²⁹ and Miedema et al.³⁶). TNO recognized that outdoor nighttime noise exposure at the most exposed facade of a dwelling (in terms of L_{night}) is not the only acoustical factor that influences sleep disturbance. Therefore, attention is being given to the role of other factors, notably the actual noise exposure at the facade of the bedroom and the difference between outdoor and indoor noise levels (sound insulation) of bedrooms. There is also concern about whether using only a metric that describes the whole night exposure, such as L_{night} , is sufficient or whether an individual event metric is also needed. Vallet³⁷ has argued for a

Figure 1 Finegold and Elias⁴¹ sleep disturbance prediction curve and earlier FICON³⁹ interim curve.

supplementary indicator, L_{\max} , to be used in addition to L_{night} .

10.2 Sleep Disturbance Exposure–Response Relationships in the United States

In an early but quite important study, Pearsons et al.³ compiled a comprehensive database representing over 25 years of both laboratory and field research on noise-induced sleep disturbance due to a variety of noise sources. This database was the basis for an interim curve recommended by Finegold et al.³⁸ to predict the percent of exposed individuals awakened as a function of indoor A-weighted sound exposure level (ASEL). This curve was adopted by the U.S. Federal Interagency Committee on Noise (FICON)³⁹ as an “interim” sleep disturbance curve with the caveat that additional research was needed. Since the publication of the FICON report, a series of additional field studies were conducted in the United States to further investigate noise-induced sleep disturbance from transportation noise sources, primarily aircraft noise, in various residential settings. Based on this series of field studies, BBN Laboratories developed an exposure–response relationship, which was recommended in the U.S. ANSI Standard S12.9, Part 6, Methods for Estimation of Awakenings Associated with Aircraft Noise Events Heard in Homes.⁴⁰ The BBN Laboratories metaanalysis was redone with some changes in the metaanalysis approach, as described in Finegold and Elias.⁴¹ The results of this new metaanalysis are

shown in Fig. 1. The 1992 FICON curve is also shown in this figure for comparison purposes.

Three of the eight studies included in this database contained data on road traffic noise exposure, and thus it is deemed at least minimally sufficient to use this curve in predicting sleep disturbance due to road traffic noise. Six of the eight studies included data from aircraft noise exposures, but only one study contributed data on railway noise. Thus, sleep disturbance due to railway noise is the weakest part of the database. However, the final predictive curve averages together the responses to all transportation noise sources, making it, on average, reasonably applicable to all three transportation noise source categories: aircraft, road traffic, and railways. However, the Finegold and Elias⁴¹ predictive curve only accounts for about 22% of the overall variance in the data. This means that sleep disturbance researchers are still not able to make very accurate predictions of sleep disturbance, especially at the community level. The reason for this is that there are many nonacoustic factors that affect people’s responses to noise during sleep in addition to the level and spectral properties of the intruding noise.

Figure 1 can be used to predict the level of sleep disturbance expected as a result of community development projects, such as adding an additional runway at an airport or changing a two-lane road into a major thoroughfare, where the future noise exposure can be modeled or otherwise estimated. For projects such as these that involve government funding, an environmental impact analysis is typically required. Noise issues, such as community annoyance

and sleep disturbance, are often highly controversial components of such an analysis. Accurate prediction of the effects of noise on affected communities is the foundation of informed noise management decisions and is a critical component of the environmental impact analysis process (see Chapter 127 of this handbook for a discussion of this topic).

11 EXPOSURE CRITERIA FOR ASSESSING SLEEP DISTURBANCE

The most common metrics for assessing the impacts of community noise, such as the day–night average sound pressure level (DNL), already contain a strong 10-dB penalty for nighttime noises, and community noise exposure policies typically do not include separate criteria for sleep disturbance. However, there are circumstances where a separate analysis of the impacts of nighttime noise is warranted. The World Health Organization¹ recommends that the indoor sound pressure levels should not exceed 45 dB L_{AFmax} more than 10 to 15 times per night for individual intrusive events and should not exceed an 8-h, equivalent continuous A-weighted sound pressure level ($L_{Aeq,8h}$) of 30 dB for continuous total-night noise exposure in order to avoid negative effects on sleep, especially for transportation noise sources. WHO allows the use of either L_{AFmax} or SEL as the exposure metric. For intermittent events that approximate aircraft noise, with an effective duration of 10 to 30 s, values of 55 to 60 dB SEL correspond to an L_{AFmax} value of 45 dB. These criteria, however, do not take into account the practicality of achieving these goals. This understanding is important to efforts to implement the recommended criteria at the community level. According to WHO,¹ “the evaluation of (noise) control options must take into account technical, financial, social, health and environmental factors. . . . Cost-benefit relationships, as well as the cost-effectiveness of the control measures, must be considered in the context of the social and financial situation of each country.” WHO intended that these criteria be used as part of an environmental noise management decision-making process for which the environmental noise impact analysis process is one of the central issues, for managing impacts such as sleep disturbance. Most countries, including the United States, do not yet have noise exposure criteria specifically to address potential sleep disturbances in communities, although many European Union countries are considering taking this step, especially in the vicinity of large airports with numerous nighttime flight operations. Of course, it is true that assumptions about average attenuation value of housing sound insulation to meet indoor noise exposure criteria are only valid with the windows closed, even though this reduces the overall air quality in the bedroom.

In an environmental impact analysis or other use of the WHO criteria, it is important to remember that the exposure criteria is just one point along an exposure–response curve, and that these criteria are only “guidelines” not regulations. The overall environmental noise decision-making process should also consider

the cost and technical trade-offs involved in attempting to meet any particular exposure criterion. This allows some flexibility in addressing the engineering and financial issues involved in trying to meet the recommended exposure goals, rather than simply strictly applying exposure criteria without these considerations being taken into account.

12 SUMMARY

Although the most common metrics for assessing the impacts of community noise, day–night average sound pressure level (DNL) and day–evening–night average sound pressure level (DENL), already contain a 10-dB penalty for nighttime noises, there are circumstances where a separate analysis of the impacts of nighttime transportation noise is warranted, particularly in environmental impact analyses and related efforts. There are, however, different definitions of sleep disturbance and different ways to measure it, different exposure metrics that can be used, and consistent differences in the results of laboratory versus field studies. At the present time, very little is known about how, why, and how often people are awakened during the night, although it is generally acknowledged that the “meaning of the sound” to the individual, such as a child crying, is a strong predictor of awakening. More importantly, very little is known about the *long-term, cumulative effects* of intermittent sleep disturbance from community noise exposures.

This chapter briefly discussed the various approaches used in sleep disturbance research and presented the best information currently available to describe the exposure–response relationship between transportation noise exposure and sleep disturbance, although existing sleep disturbance databases for transportation noise sources contain considerably more data for aircraft noise exposure than for exposure to road traffic or railway noise. There are large differences between communities in their responses to community noises. Some of the reasons for this include differences in the characteristics of the noise itself, differences in individual sensitivities, differences in attitudinal biases toward the noise source, and the context of the living environment. Current exposure–response relationships use either “awakenings” or “body movements” to describe sleep disturbance.

Finally, this chapter also briefly discussed the issue of noise exposure criteria for sleep disturbance and how to use existing criteria in making community noise management decisions. The World Health Organization¹ has recommended that nighttime indoor sound pressure levels should not exceed approximately 45 dB L_{AFmax} more than 10 to 15 times per night. For intermittent events similar to aircraft overflights, with an effective duration of 10 to 30 s, this corresponds to indoor values of 55 to 60 dB SEL. According to WHO, either L_{AFmax} or SEL may be used if the noise is not continuous. For total night exposure, a criterion of 30 dB $L_{Aeq,8h}$ was recommended for use in combination with the single event criterion (L_{AFmax} or SEL). At the present time, the WHO exposure criteria are

recommended for general transportation noise sources. It needs to be pointed out, however, that the criteria recommended by WHO are long-term targets and do not take into consideration the cost or technical feasibility of meeting their recommended ideal maximum exposure levels. WHO intended that these criteria be used as part of a noise management decision-making process, for which environmental noise impact analysis is the central issue. The Finegold and Elias⁴¹ exposure-response curve allows consideration of the different levels of impact predicted at various levels of exposure and is recommended for use in predicting sleep disturbance in communities due to exposure to transportation noise, particularly aircraft noise.

CHAPTER 25

NOISE-INDUCED ANNOYANCE

Sanford Fidell
Fidell Associates, Inc.
Woodland Hills, California

1 INTRODUCTION

Annoyance is the adverse attitude that people form toward sounds that distract attention from or otherwise interfere with ongoing activities such as speech communication, task performance, recreation, relaxation, and sleep. With respect to annoyance, noise is not merely *unwanted sound*, but rather unbidden sound that someone *else* considers too inconvenient to control. No matter how sophisticated methods for predicting annoyance from purely acoustic variables become, annoyance remains at root a property of an unwilling listener. It is a listener engaged in ongoing activities, not a sound level meter or a computational algorithm, that is annoyed by noise.

Annoyance differs from loudness in its dependence on duration and context. Once a sound attains a duration of about a quarter of a second, it grows no louder. The annoyance of a sound, however, continues to grow in direct proportion to its duration. Further, although the loudness of a sound is fully determined by its acoustic content, the annoyance of a sound may vary considerably with the activity in which a listener is engaged at the time of its occurrence, and with its meaning. Great individual and contextual differences in sensitivity to the annoyance of sounds are more the rule than the exception.

2 ABSOLUTE ANNOYANCE OF INDIVIDUAL SOUNDS

The basic acoustic correlates of the annoyance of sounds are their level, duration, spectral content, frequency of occurrence, and—particularly in a community noise setting—time of day of occurrence. As a generality, higher level, longer duration, more frequently occurring, and higher frequency sounds tend to be more annoying than lower level, shorter duration, less frequently occurring, and lower frequency sounds. Second-order properties of the character of sounds (e.g., tonality, impulsiveness, phase, complexity, and harmonic structure) can also contribute to their annoyance, as can nonacoustic factors such as novelty, fear, economic dependence, attitudes of misfeasance and malfeasance, learned associations and aversions, and the like.

As a further generality, sounds that are more readily noticed in the presence of commonplace ambient noise environments (such as those with prominent tonal, narrow-band, high-frequency, or otherwise distinctive spectral content; cyclical or repetitive sounds; and sounds that are less masked by background noise) are likely to be considered more annoying than the

complementary sorts of sounds. A level of audibility roughly an order of magnitude greater than that required for simple detection of sounds in an attentive listening task is required for sounds to reliably intrude upon the awareness of people absorbed in unrelated ongoing activities.¹

Note, however, that intermittent and unexpected sounds of relatively low level occurring in low-level indoor noise environments (e.g., dripping faucets, a key in a doorknob, or a footfall in a quiet bedroom at night, mechanical squeaks and rattles, heel clicks, or indistinct conversation in adjacent living quarters) can also be highly annoying.^{2,3} The annoyance of such low-level sounds is related to their bandwidth-adjusted signal-to-noise ratio (“noticeability”) but exacerbated by nonacoustic factors such as their unexpectedness, novelty, and meaning. In fact, the annoyance of even higher level noise events (e.g., barking dogs, children playing, or motorcycle drivebys) may be more greatly influenced by nonacoustic and contextual factors than by their physical properties.

3 RELATIVE INFLUENCES OF ACOUSTICAL AND NONACOUSTICAL FACTORS ON ANNOYANCE JUDGMENTS

Laboratory studies provide the strongest evidence of the predictive utility of frequency-weighting procedures for assessments of noise-induced annoyance. The judgments of people asked under controlled listening conditions to compare the annoyance of artificial or meaningless sounds such as tones and bands of noise are generally well predicted by spectral weighting procedures. For example, A-level is consistently found to be superior to unweighted (overall) noise metric as a predictor of annoyance^{4,5} and measures such as effective perceived noise level⁶ account well for the effects of signal duration on annoyance. Note, however, that sounds of identical equivalent level and power spectra but different phase spectra, which are indistinguishable to a sound level meter, can vary greatly in their judged annoyance.⁷

More complex metrics such as loudness level^{8,9} that are level- as well as frequency-dependent are yet better predictors of laboratory annoyance judgments.¹⁰ In applications such as prediction of automotive sound quality, attributes such as “harshness,” or “roughness,” and even more elaborate descriptors are commonplace. These descriptors, which are sensitive to higher order acoustical properties such as harmonic and phase structures of individual sounds, have gained popularity for evaluations of the sound quality of mechanical

sources, including gear, pump, air intake and exhaust, electric motor, chassis and suspension, and door slam.¹¹

Outside of controlled laboratory settings, accurate prediction of the annoyance of cumulative, long-term noise exposure has proven more elusive. Sounds of relatively low signal-to-noise ratio are sometimes judged to be disproportionately annoying,^{2,12} while sounds of relatively high absolute level (e.g., those of rail and road traffic) may be considered less annoying than sounds of comparable A-weighted level produced by aircraft.^{13–15} No population-level dosage–response relationship for predicting the prevalence of annoyance from cumulative, long-term noise exposure has yet accounted for the better part of the variance in annoyance prevalence rates in communities.^{15–17}

The contrast between the utility of frequency-weighted noise metrics as descriptors of noise-induced annoyance in laboratory settings on the one hand and their obvious shortcomings in everyday circumstances of environmental noise exposure on the other has given rise to persistent doubts¹⁸ about the practical utility of noise descriptors that are based on complex frequency-weighting methods. These doubts extend to the rationale for interpreting the tolerability of environmental noise exposure via noise metrics that are better predictors in laboratory than residential settings.

Much uncertainty continues to surround (1) the nature and number of acoustical parameters that could arguably improve the adequacy of noise descriptors as predictors of annoyance in residential settings; (2) the necessity of accounting for context dependency of annoyance judgments; (3) the relative influences of nonacoustic factors on annoyance judgments (e.g., time of day, frequency and regularity of noise intrusions, attitudes and situation-dependent expectations about noise sources and their operators, locus of control over exposure, and demographic factors); and (4) parsimonious ways to accommodate additional predictive parameters.

4 NATURE OF NOISE METRICS INTENDED TO PREDICT ANNOYANCE

Most descriptors of individual and multiple noise events used to predict annoyance correlate more highly with one another than with annoyance judgments. No amount of specification of the spectral content, level, crest factor, harmonic complexity, dynamic range, or bandwidth-adjusted signal-to-noise ratio of individual noise events guarantees a precise account of the likelihood or degree to which an individual will judge them to be annoying.

Two types of acoustical descriptors have been developed to predict the annoyance of sounds: Those intended to account for source-specific judgments of the annoyance of individual events and those intended for use in assessments of environmental noise impacts. The former descriptors are more complex, detailed, and expensive to measure or calculate and, hence, most appropriately used in a few applications where their costs are justifiable. For

example, for purposes of aircraft noise certification, Part 36 of the U.S. Federal Aviation Regulations requires elaborately controlled measurements of tone- and duration-corrected perceived noise levels.

For larger scale analyses, such as gauging community-level reaction to prospective transportation noise exposure, less complex, A-weighted noise level descriptors such as day–night average sound pressure level, are commonplace.^{19,20} These measures of cumulative noise exposure combine into a single index—and thus inextricably confound—all of the primary characteristics of noise events that could plausibly give rise to noise-induced annoyance. Regulatory efforts to predict community annoyance from acoustical measurements alone are typically driven by administrative convenience, expedience, and commercial interest, rather than by theory-based, scientific understanding of causes and mechanisms of annoyance. The rationale for combining level, duration, spectral content, and frequency and time of occurrence, and for ignoring all of the secondary and nonacoustic determinants of annoyance, is provided by the *equal-energy hypothesis*—the notion that sounds of identical energy content are equally annoying. This is a simplification adopted for the sake of tractable analyses of the complexity and variability of community noise exposure.

5 DIRECT MEASUREMENT OF THE ANNOYANCE OF SOUNDS

Most empirical procedures for direct measurement of the annoyance of individual sounds are adaptations of classical psychophysical techniques such as the methods of limits and of adjustment. The most readily interpretable of these methods solicit direct comparisons of the annoyance of pairs of sequentially presented sounds. In adaptive paired comparison experimental designs, for example, test participants typically listen to a pair of sounds (one constant and one variable) within a given trial and judge which of the pair is the more annoying before the start of the next trial. Presentation levels (or durations, or spectral content, or any other manipulable signal property) of the variable signal are adjusted according to test protocols on successive presentations to yield estimates of points of subjective equality of annoyance, or other specifiable points on psychometric functions.

Less direct procedures for gauging the annoyance of sounds are also common, including variants of magnitude estimation (in which numbers are assigned in proportion to the judged intensity of sensations), semantic differential (in which judgments are solicited of the degree to which sounds possess variously described qualities), cross-modality matching (in which the annoyance of sounds is matched to some other perceptual quantity), and absolute judgment techniques (in which test category labels are assigned to the annoyance of sounds). In community settings, procedures for conventional social survey and questionnaire design are also well established.²¹

6 COMMON SOURCES OF NOISE-INDUCED ANNOYANCE IN COMMUNITY AND OTHER SETTINGS

In motorized urban society, transportation-related sources are by far the most pervasive and annoying sources of community noise exposure.* Airport-related noise is the highest level and the most extensively studied form of transportation noise, even though it consequentially annoys only a small proportion of the urban population worldwide. Noise created by aircraft en route is a common source of annoyance throughout many suburban and rural areas, albeit at cumulative exposure levels considerably lower than in the vicinity of airport runways.

In high population density urban life, characterized by extensive indoor living, noises created in adjacent dwelling units (heel clicks, door slams, plumbing and high-volume air handling noise, household appliances, electronic entertainment, indistinct conversation, etc.) and street sounds (including emergency vehicle warning signals, garbage collection, and crowd noise) are salient sources of noise-induced annoyance, even when not heard at absolute levels as great as those characteristic of outdoor transportation sources. Rattling sounds produced as secondary emissions by household paraphernalia and by doors, windows, ducts, and other light architectural elements excited by low-frequency noise or vibration from remote sources are also common sources of annoyance in residences.³

7 ANNOYANCE AS THE BASIS OF U.S. FEDERAL POLICY ON SIGNIFICANCE OF COMMUNITY NOISE IMPACTS

Despite the limited success of efforts to predict annoyance from exclusively physical measures of noise exposure, annoyance remains the summary measure of environmental noise effects favored by U.S. federal agencies. According to the Federal Interagency Committee on Noise,²² “the percent of the [noise] exposed population expected to be Highly Annoyed (%HA) [is] the most useful metric for characterizing or assessing noise impact on people.” The prevalence of a consequential degree of annoyance in a community (percentage highly annoyed, or %HA) is simply 100 times the number of people who describe themselves as highly annoyed when their opinions are directly solicited in a social survey, divided by the total number of people interviewed. In this context, the distinction between “individual annoyance” and “community annoyance” is merely one of level of aggregation.

*In typical residential settings and on a nationwide basis, noise produced by industrial activities (including electrical power production and distribution, refinery and manufacturing noise, automotive repair, quarry blasting, etc.), by construction, by military training operations, and by a large miscellany of other sources are more localized and affect far fewer people than transportation noise.

FICON²² has not only adopted annoyance as its preferred “summary measure of the general adverse reaction of people to noise” for assessment of community-level environmental noise effects, but also endorsed a specific fitting function as its preferred dosage–effect relationship:

$$\%HA = 100 / (1 + e^{11.13 - 0.141L_{dn}})$$

Although officially endorsed, FICON’s dosage–effect relationship accounts for only 19% of the variance in aircraft noise annoyance data and is not a reliable source of accurate or precise predictions of the annoyance of transportation noise exposure. Miedema and Vos¹⁵ have suggested alternate, source-specific fitting functions for road, rail, and airborne noise sources. Fidell¹⁷ and Fidell and Silvati²³ have documented large errors of prediction and other limitations of FICON’s relationship.

A major attraction of a dosage–effect relationship between cumulative noise and annoyance is that it permits treatment of community-level noise effects in acoustical terms and serves as an ostensible underpinning for “land-use compatibility” recommendations expressed in units of decibels. Such recommendations provide the form, if not the substance, of a rationale for gauging the “acceptability” of noise in residential and other circumstances of exposure.¹⁷

8 RELATIONSHIP BETWEEN ANNOYANCE AND COMPLAINTS IN COMMUNITY SETTINGS

Because annoyance is a covert mental process, self-report in response to a structured interview is its only direct measure. Complaints are an unsolicited form of self-report of dissatisfaction with noise exposure. Although the attitude of annoyance and the behavior of complaining are both manifested through self-report, they are not synonymous, and annoyance may not be the sole cause of complaints. Both forms of reaction to noise exposure are affected by acoustical and nonacoustical factors and thus reflect the combined influences of “true” sensitivity to physical characteristics of exposure and of response bias.[†] FICON²² observes that “annoyance can exist without complaints and, conversely, complaints may exist without high levels of annoyance” and concludes that annoyance is a more reliable indication of environmental noise impacts than complaints. It is equally true, however, that high levels of noise-induced annoyance can exist at low levels of noise exposure, and that low levels of annoyance can exist at high levels of noise exposure. Thus, lack of a

[†]Signal detection theory^{24,25} Green and Swets, 1966; offers a systematic framework for analyzing the independent contributions of sensitivity and response bias to any decision process. Viewing a self-report of the form “I’m highly annoyed by the noise of that aircraft flyover” as the product of a decision-like process provides a theory-based avenue to analysis of the annoyance of community noise exposure.

simple relationship between noise exposure and its effects is not a persuasive rationale for a narrow focus on annoyance, to the exclusion of complaints, as a meaningful indication of community response to noise.¹⁷

In practical reality, it makes no more sense to ignore noise complaints because they may or may not be closely related to annoyance than to ignore annoyance because it may or may not be closely related to complaints. Whether reports of adverse consequences of noise exposure are solicited or unsolicited is of importance more for administrative reasons than for evaluating actual noise impacts. Geographic distributions of complaint densities (complaints per unit time per unit area) can also yield important clues about reactions to community noise exposure that are not apparent from simple annoyance prevalence rates.¹⁷

CHAPTER 26

EFFECTS OF INFRASOUND, LOW-FREQUENCY NOISE, AND ULTRASOUND ON PEOPLE

Norm Broner
Sinclair Knight Merz
Melbourne, Australia

1 INTRODUCTION

Infrasound, low-frequency noise, and ultrasound have different effects on people. Infrasound is sound below 20 Hz, which is often inaudible, while low-frequency noise (LFN) is in the range of 20 to 100 Hz and audible. Ultrasound, on the other hand, includes noise in the high-frequency range above 16 kHz. Many of the effects attributed to infrasound are actually due to low-frequency noise in the region of 20 to 100 Hz.

In general, for sound pressure levels that occur in our everyday life, the low-frequency effects are not found to be significant in terms of causing long-term physiological damage. However, short-term changes in physiological responses and in performance can occur following exposure. Annoyance due to infrasonic, low-frequency, and ultrasonic exposure can also result from longer duration exposures (hours to days). Recent studies seem to show that low-frequency noise in the region of 20 to 50 Hz has a more significant effect on people than either infrasound or ultrasound at normal exposure levels.

2 INFRASOUND

Infrasound is generally considered to be sound at frequencies below 20 Hz. Many sources of infrasound and LFN have been identified, including air-conditioning systems, oil and gas burners, boilers, and noise inside transportation.¹⁻⁴ Many of these sources exhibit a spectrum that shows a general decrease in sound pressure level (SPL) with increase in frequency, and it is now apparent that the spectrum imbalance is a major source of subjective annoyance due to exposure to this type of sound. Subjective reports of disorientation, headache, and unpleasantness have been reported even where the A-weighted sound pressure level is relatively low.

In the 1960s and the 1970s and occasionally since, sensationalized reports of the “dangerous” nature of infrasound were reported, creating “panic” among some. Brain tumors, cot death, and “mashed intestines” were all “blamed” on infrasound in particular.^{1,3} These reports have not been validated and have been the cause of misinformation and unnecessary angst by some members of the public.

Levels of infrasound, up to 150 dB, have been found to be tolerable for shorter exposures, and 24-h exposures up to 120 to 130 dB were found to be “safe” from a physiological point of view.^{1,3} At these levels, the infrasound was generally considered quite

unpleasant subjectively, however, at levels at which infrasound normally occurs, that is, 90 to 110 dB (depending on frequency), the sound is generally potentially annoying only with relatively low potential for side effects.

2.1 Hearing Threshold

Many studies have been conducted to determine the infrasonic and low-frequency hearing threshold and loudness curves, and there is a general consistency among the results⁵ (see Fig. 1). First, it appears that below around 15 Hz, there is a change in response to that of “sensation” or “presence” rather than that of “hearing.” ISO 226⁶ provides equal-loudness-level contours based on pure tones under free-field listening conditions. This revised standard considered various research work, particularly since 1983 and as recent as 2002, and specifies contours, including the hearing threshold from 20 Hz up to 12,500 Hz. With respect to low-frequency noise, the work of Watanabe and Moller⁷ was considered (see Fig. 1). This work gives the threshold as 107 dB at 4 Hz, 97 dB at 10 Hz, and 79 dB at 20 Hz, which coincides very nearly with the ISO 226⁶ threshold curve at 20 Hz. Note that at about 15 Hz, there is a change of the threshold slope from approximately -20 dB/octave at higher frequencies to -12 dB/octave at lower frequencies. This change seems to reflect the change from a “hearing” perception above 15 Hz to one of “pressure,” particularly at higher SPLs. Note also that the hearing thresholds are mean values and that the standard variation about the mean is not insignificant.⁵ This means that, on an individual basis, the threshold could be up to say, 5 to 10 dB lower or higher than the mean. For example, Frost⁹ compared two subjects, one of whom was 15 dB more sensitive at 40 Hz than the other but had similar audiograms at 250, 500, and 1000 Hz.

Note that at low and particularly infrasonic frequencies, the loudness contours are much closer together so that for a given change in SPL (increase or decrease), the change in loudness is much greater at low frequencies than the same SPL change at high frequencies. For example, the difference between the 20- and 80-phon curves is 60 dB at 1000 Hz but only 15 dB at 8 Hz. Thus, the fluctuations in perceived loudness as a result of the level fluctuations will be considerably larger than at higher frequencies. This could be the explanation for the increased reported annoyance due to LFN and infrasound.

Figure 1 Comparison of threshold data. (From Watanabe and Moller.⁷ Reprinted by permission.)

In addition, the thresholds for low-frequency complex noises appear to be *lower* than the pure-tone thresholds.^{5,10,11} Thus, it appears there is an increased sensitivity to complex LFN such as heating, ventilation, and air-conditioning (HVAC) noise as compared to pure tones.

2.2 Temporary Threshold Shift (TTS)

A quantitative relationship between human exposure to infrasound and hearing loss is not well established, and this is partly due to the inability to produce infrasound exposures without audible overtones. It appears that (1) only small, if any, TTS can be observed following exposure to moderate and intense infrasonics, and (2) recovery to preexposure levels is rapid when TTS does occur. Similarly, it appears that LFN will produce TTS in some subjects after short exposure, but that recovery is rapid and complete. However, there is an indication that long-term exposure to very high levels may cause permanent hearing loss.¹⁻³

2.3 Threshold of Pain

Low-frequency noise and infrasound at a higher level is less likely to result in hearing loss as compared to higher frequency sound at a similar level. The threshold of pain appears to be about 135 dB around 50 Hz, 140 dB around 20 Hz, increasing to about 162 dB at 2 Hz and 170 to 180 dB for static pressure.¹²

2.4 Annoyance

The primary effect due to infrasound and LFN appears to be annoyance. It can be said that the effects of infrasound and LFN are broadly similar to those of high-frequency noise in the sense that any unwanted sound is potentially annoying. However,

LFN and infrasound often exhibits itself in the form of “rumble” and “pressure,” and the sound pressure level fluctuations can exacerbate the annoyance reaction when compared to higher frequency noise.^{13,14}

Broner and Leventhall¹⁵ found that unless the conditions are optimized for differentiating sounds with respect to loudness and annoyance, subjects treated them in approximately the same way. It seems that for sound with “tonal” low-frequency content below 50 Hz and for infrasound, particularly where the sound pressure level is perceptibly fluctuating or throbbing, annoyance and loudness are treated differently and that this difference may increase with time.¹⁶ As the loudness adapts more rapidly with time than the annoyance (i.e., the perceived loudness decreases more rapidly with time than the perceived annoyance), the effect is to effectively increase the annoyance with time. This effect would be worse for infrasound where the sound is not so much heard but is perceived rather as a feeling and sensation of pressure.

2.5 Annoyance Assessment

Assessment and prediction of annoyance due to infrasound and LFN is not simple. What is very clear is that the A-weighted SPL alone is **not** successful in assessing the response to infrasound and LFN.¹⁻³ A review of case histories indicates that very annoying sounds often have rather low A-weighted SPL but nevertheless cause significant annoyance. This is due to the presence of an unbalanced spectrum, which additionally may have an amplitude and/or temporal fluctuating characteristic.

Empirical evidence shows that where the imbalance is such that the difference between the linear and A-weighted SPL is at least 25 dB, the sound is likely

to cause annoyance. Broner and Leventhall¹⁵ and DIN 45680-1997¹⁷ suggested that a difference of 20 dB can result in an unbalanced spectrum that could lead to LFN annoyance. Others suggested that a difference of only 15 dB was a good rule of thumb to identify a potential infrasound LFN problem situation.^{14,18} In general, it seems that the (C—A) level difference is appropriate metric for indicating a potential LFN problem but that its predictive ability is of limited value.⁸

The perception of annoyance is particularly dependent on the degree of amplitude modulation and spectral balance,^{19,20} and, as a result, it is considered that there is a significant limitation in the long-term averaging of infrasonic and LFN noise levels, as this approach results in the loss of information on fluctuations.^{15,21}

Broner and Leventhall¹⁵ recognized the problem of spectrum imbalance for assessment of infrasound and LFN complaints and proposed the low-frequency noise rating (LFNR) curves. These significantly reduced the infrasonic and low-frequency energy allowed by the noise rating (NR) curves. Further attempts at diagnostic assessment of room noise incorporated

elements of sound quality. Blazier²² used 16 years of practical experience and data from Broner²³ to refine the earlier RC (room criterion) procedure for rating HVAC system-related noise in buildings developed by Blazier.²⁴ The refinement included a modification to the shape of the RC reference curves in the 16-Hz octave band (see Fig. 2), an improvement in the procedure for assessment of sound quality and the development of a scale to estimate the magnitude of subjective response as a function of spectrum imbalance, the “quality assessment index” (QAI). The method was designated the RC Mark II and this method allows the calculation of spectrum quality by calculating the balance of low, mid, and high frequencies. This method is preferred by the American Society of Heating, Refrigeration, and Air Conditioning Engineers (ASHRAE).²⁵ Note that the America National Standards Institute (ANSI) S12.2-1995²⁶ included both the RC method and the balanced noise criteria (NCB) method developed by Beranek.²⁷ This author feels strongly, based on empirical evidence,¹⁵ that the NCB curves, which apply to occupied spaces, are much too lenient in the

Figure 2 Family of room criterion (RC Mark II) reference curves. (Originally published by Warren E. Blazier.²² Reprinted by permission.)

16 and 31.5-Hz octave bands and that the LFNR and RC Mark II methods are much preferred.

The G-weighting (ISO 7196-1995²⁸) was specifically designed for assessment of infrasound, falling off rapidly below 1 Hz and above 20 Hz at 24 dB/octave. Between 1 and 20 Hz, it follows a slope of 12 dB/octave, thus each frequency is weighted in accordance with its relative contribution to the perception. Note that this feature may result in an underestimation of loudness at frequencies between about 16 and 20 Hz.²⁹ A G-weighted sound pressure level of 95 to 100 dB is close to perception level, while G-weighted levels below 85 to 90 dB are not normally significant for human perception. Note also that (1) due to the combined effect of individual differences in perception threshold and the steep rise in sensation above the threshold, the same infrasonic noise may appear loud and annoying to some people, while others may hardly perceive it.²⁸ (2) This weighting has a limited application in practice, and care should be taken not to put too much reliance on this metric as it may divert attention away from problems at higher frequencies. In practice, for commonly occurring noise levels, LFN in the range of 30 to 80 Hz is more likely to be a problem in terms of annoyance.³

2.6 European Assessment Criteria

A number of different European methods have also been suggested for assessment of infrasound and LFN, all based on measured indoor noise levels. These are the Danish,²⁹ Swedish, German, Polish, and Dutch methods (Poulsen³⁰ and Leventhall⁸ compare all of these). Each of these has different criteria for the allowed noise level, and the administrative procedures used in the individual countries to enforce the criteria are very different. Figure 3 shows a comparison of the various criteria curves.³⁰ Some of these methods also address the issue of fluctuations in level that have

been identified as a major cause of annoyance due to LFN, for example, DIN 45680.¹³ A Working Group CEN/TC 126/WG1 linked to ISO/TC 43/SC 2 "Building Acoustics" is also working on two new European standards concerning the methods of measuring noise from service equipment in buildings.³¹

2.7 Performance Effects

Over the last few years, due to the prevalence of infrasonic and LFN sources such as ventilation/air conditioning, pumps, diesel engines, and compressors and due to the growing body of data showing the prevalence of low-frequency noise problems/effects, there has been interest in their impact in the workplace.^{14,32-34} In terms of performance, infrasound and LFN is reported to cause drowsiness, fatigue, and headaches and can result in performance effects, possibly due to information processing overload. Low-frequency ventilation noise has been shown to affect a mentally demanding verbal reasoning task and work efficiency, and quality was found to be impaired. Further, LFN has been found to impair performance on tasks with high and moderate demands on cognitive processing when performed under high workload. LFN has also impaired performance on some of the low-demand tasks and a moderately demanding verbal task under low workload.³³ Thus the impact of LFN on performance is demonstrable under certain circumstances, and the significance of the impact is dependent on the nature of the work and the circumstances of that work, just as for higher frequency noise impact. It is likely that complex tasks and a long exposure would result in a measurable performance effect similar to the impact of higher frequency noise. Available evidence also suggests that infrasound even at very intense exposure levels is not detrimental to human performance.¹²

Figure 3 Comparison of criteria curves from the different assessment methods. (From Poulsen.³⁰ Reprinted by permission.)

2.8 Physiological Effects

Physiological responses have been observed including cardiac rhythm and respiration rate [measured by electrocardiogram (EKG) recordings, pulse counts, and impedance pneumography], vasoconstriction and vasodilation, change of systolic rhythm, blood and endocrine changes, changes in cortisol levels, and disturbances to the central nervous system. The data suggests that any of these effects are unlikely to be of any practical importance except under extreme occupational exposure.^{34–36}

2.9 Sleep Effect

There is some evidence that exposure to LFN results in reduced wakefulness or increased tiredness and a feeling of fatigue. The practical significance of this may be a reduced reaction time, which may be important in some situations, for example, driving on a freeway.^{37,38}

3 ULTRASOUND

Ultrasound usually is considered to cover sound in the range of 16 to 40 Hz. There are many industrial and commercial sources of infrasound, for example, ultrasonic cleaners, welders, atomizers, and electroplaters. Due to the very high frequency, the wavelength of ultrasound is very small, of the order of 5 to 20 mm. Because of this, ultrasound is readily absorbed in the air and is readily attenuated by distance from the source and by normal building materials. Also, due to the impedance mismatch with the human body, the ear is usually the primary channel for transmitting airborne ultrasound to a person. Therefore, people who do not “hear” in the ultrasonic region usually do not display any of the subjective symptoms.

3.1 Ultrasonic Levels and Subjective Effects

Exposure to industrial ultrasonic devices rarely exceeds 120 dB, and exposure to commercial devices designed to emit ultrasound rarely exceeds 110 dB. Commercial devices that incidentally emit ultrasound, such as video display terminals, rarely exceed 65 dB at the operator's ear.³⁹ Note that many industrial and commercial processes that generate high levels of ultrasound also generate high levels of subharmonics, that is, sound at “sonic” frequencies. These sonic exposures cannot be ignored in considering the hazards of industrial ultrasonic exposure as it is often the sonic frequencies that are more hazardous for equivalent SPLs and that are the cause of the subjectively reported effects such as fullness of the ear, tinnitus, fatigue, dizziness, and headache.⁴⁰

It appears that direct contact exposure to high-level ultrasound may cause a sharp pain or possibly a “burn,” but documented cases of actual tissue damage are rare. In any case, direct contact is usually due to an accident or carelessness. More normal is exposure to airborne ultrasound via the ear.

3.2 Hearing

The average threshold of hearing increases rapidly and monotonically with frequency at a rate of the

order of 12 dB/Hz between 14 and 20 Hz leading to a threshold of 100 dB at 20 Hz and 125 dB at 25 Hz. There are some reports that a temporary hearing loss may occur due to high-level ultrasound (>140 dB), but recovery seems to be complete and rapid. SPLs lower than 120 dB have not been demonstrated to cause hearing losses. Physiological effects (e.g., disturbance of neuromuscular coordination, dizziness, loss of equilibrium) appear to occur only at SPLs greater than that which causes TTS.

3.3 Criteria

The data indicates that when people are subjected to ultrasound without the audible components, no complaints are received. To avoid subjective affects for the unprotected ear, Acton⁴¹ recommended criterion limits of 75 dB from 16 to 20 Hz and less than 110 dB for frequencies greater than 20 to 50 Hz, and these criteria seem to have been generally adopted. For frequencies between 10 and 20 Hz, the Occupational Safety and Health Administration (OSHA)⁴² recommends a ceiling value of 105 dB to prevent subjective annoyance and discomfort, especially if the sounds are tonal in nature. It is noted, however, that subjective annoyance and discomfort may occur in some individuals at levels between 75 and 105 dB. Health Canada³⁹ also recommends a limit of 137 dB in the ultrasonic range to avoid the potential of mild heating effects. Occupational health and safety procedures are similar to those used for audible noise with the objective to ensure that ambient SPLs do not exceed the recommended maximum permissible exposure level.

CHAPTER 27

AUDITORY HAZARDS OF IMPULSE AND IMPACT NOISE

1 INTRODUCTION

High-level transient noise presents a special hazard to the auditory system. First, impulse noise may damage the cochlea by direct mechanical processes. Second, damage risk criteria evaluate impulse noise in terms of levels, duration, and number, but parameters such as temporal pattern, waveform, and rise time are also important in the production of a hearing loss. Third, the effects of impulse noise are often inconsistent with the principle of the equal energy hypothesis. Fourth, impulse noise can interact with background noise.

2 DEFINITION OF IMPULSE NOISE

The term impulse noise is used in this chapter as a generic term that includes all forms of high-intensity short-duration sounds, that is, from the most common industrial impacts to the intense blast waves associated with military operations. The range of parameters defining an impulse is large. Impulse durations may vary from tens of microseconds for small arms fire to several hundred milliseconds for a sonic boom or a reverberant industrial impact. Intensities for these impulses may vary from less than 100 dB to in excess of 185 dB peak sound pressure level (SPL). The energy of an impulse is usually broadly distributed, but spectral concentrations of energy can occur at various frequencies throughout the audible range. The number of occurrences of impulse noise in industry or the military may vary from one impulse or less per hour to several per second with no fixed interval of time between impulses. In addition to the physical parameters of the impulse, other environmental conditions associated with the exposure can seriously affect the outcome of an exposure, that is, a free field or reverberant enclosure, angle of incidence, or the presence of other noise or vibrations, drugs, and the like.

The waveforms or signatures of impulse noise can be very different. One extreme is industrial impact noise. Impact noise is reverberant (ringing), and its physical behavior generally conforms to the laws of acoustics. At the other extreme are blast waves. They

can have peaks of 150 dB or greater and are, in fact, shock waves that are governed by physical principles that are different from the laws of acoustics.¹

Coles et al.² described two basic types of impulses: a nonreverberant A-wave and a reverberant B-wave (Fig. 1). This scheme characterizes the impulse in terms of peak level, duration, and number of impulses, but neglects a number of other potentially important variables, that is, rise time (T),³ spectrum,⁴ and temporal pattern.^{5,6} Additional working definitions of impulse noise can be found in the American National Standards Institute (ANSI) Standard S1.13 (1971), and a detailed exposition, which extends the definition,² can be found in Pfander⁷ and Pfander et al.⁸ Pfander considers the temporal specification of an impulse to include both the rarefaction and condensation phases as well as the duration of the impulse and the total number impulses.

The physical specification of the impulse is further complicated when the impulses are mixed with a continuous noise. The combination of impulse and continuous noise is very common in industrial settings. In fact, Bruel⁹ showed that crest factors of 50 dB are common. The complexity of evaluation of the hazards to hearing of a complex noise environment is currently being evaluated using kurtosis as a descriptive metric. Thus, in some circumstances, it is difficult to establish when an exposure contains impulsive components that need to be evaluated separately. Certain studies¹⁰ report a slight reduction in temporary threshold shift (TTS) produced by either agent alone. However, it is clear that under certain conditions, high-level impulses riding on a background noise produce greater injuries to the organ of Corti than either the impulse or the continuous noise alone.¹¹

In summary, there is not a consensus on how to describe the various types of impulse noise. It is not clear what combinations of impulse and continuous noise will present hearing hazards that are different from those presented by a continuous noise exposure. However, the following review of the biological and audiological effects of impulse noise shows that

Figure 1 Schematic representation of the two basic impulse noise pressure-time profiles, following the simplification of Coles et al.²

impulse noise can affect the auditory system differently than lower levels of continuous noise. Consequently, impulse noises may require special consideration when establishing future noise standards.

3 MEASUREMENT OF THE IMPULSE

There is general agreement that the best approach to measuring an isolated impulse is to record the pressure-time history of the impulse. However, because of the extreme limits of various impulse noise parameters (rise times can be as short as a few microseconds and intensities as high as 185 dB SPL), care must be given to the response properties of the measuring device. The time constant of some current impulse sound level meter (SLM) is approximately 30 to 40 ms; however, some of the shorter impulses, for example, gunfire, may last only a few hundred of a microsecond. Therefore, the limitations of the measurement system may seriously underestimate peak levels or other parameters of the impulse. However, for typical industrial types of impacts whose durations may last 200 ms or more, many of the current precision SLMs may be suitable measuring instruments.

Basically, the same considerations for a measurement system apply to impulse noise as apply to other physical systems, and general reviews can be found in Pfeiffer¹² and Nabelek.¹³ A compilation of several studies dealing with measurements can be found in Ivarsson and Nilsson.¹⁴ A suggestion was to develop computer-based instrumentation (digital techniques) to record and measure the cumulative distribution of sound pressure over the exposure period of interest.⁹ From such measurements, various methods are available to calculate total or weighted energy levels of the stimulus for application to energy-based damage risk criteria.¹⁵ While the greatest focus of measurement activity appears to be in estimating peak levels and total energies of exposure, there are other parameters, for example, presence of reflections, rise time,

and temporal pattern, that are important in determining the hazards of exposure.

Finally, there has been interest in developing instrumentation to produce a single number index of the hazards of an exposure containing impulsive components.^{15,16} These dosimeters are usually based upon some weighted measure of total energy, and generally conform to the analytical model discussed by Martin.¹⁷ While the potential value of such an instrument cannot be denied, it may be premature to adopt a measurement scheme that completely ignores a variety of potentially relevant parameters such as rise time, repetition rate, frequency content, and background noise.

4 AUDIOMETRIC EFFECTS OF IMPULSE

Experiments on monkeys,¹⁸ humans,¹⁹ and chinchillas^{20,21} have shown that the recovery from impulse noise often follows a nonmonotonic pattern, that is, there is a growth to a maximum level of TTS, as much as 10 h after exposure (Fig. 2). This pattern of recovery is much different from the typical linear (in log time) recovery pattern seen following a continuous noise exposure.²²

Furthermore, exposures that produce the nonmonotonic recovery curves usually have a prolonged period of recovery and, in most of the cases examined, have both permanent threshold shifts (PTS) and losses of sensory cells.^{21,23,24} Two investigations have developed comprehensive models of hearing loss using the results from TTS experiments. Kraak²⁵ proposed that PTS from a given exposure could be predicted by the time-integrated amount of TTS.

If subjects are exposed to a noise for a relatively long period of time, that is, on the order of days, hearing sensitivity decreases over an 8- to 48-h period and then stabilizes at an asymptotic level.^{26,27} In contrast to many of the TTS results from short-duration exposures, asymptotic threshold shift (ATS)

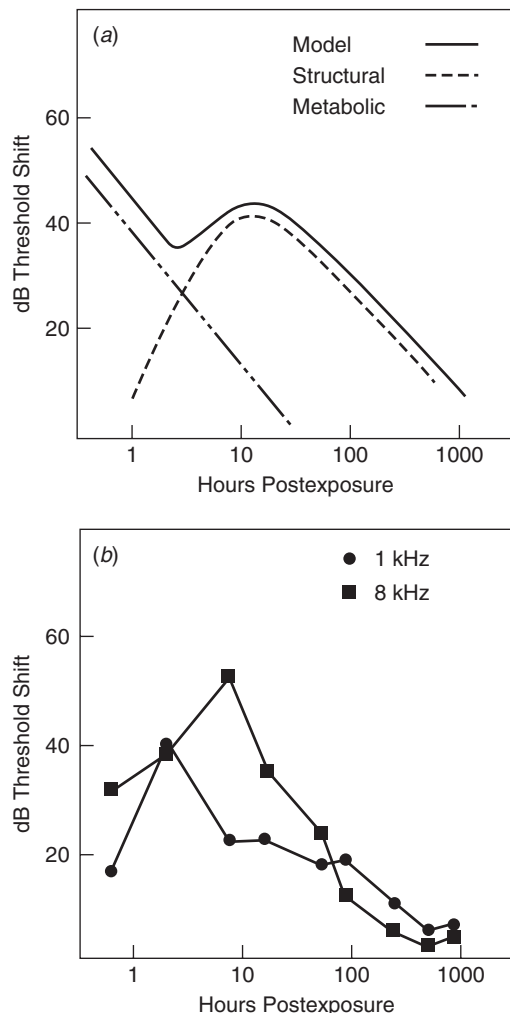

Figure 2 (a) Hypothetical threshold recovery curves illustrating the metabolic and structural recovery process for TTS associated with a model proposed by Luz and Hodge.⁶² (b) The actual TTS recovery curves for chinchillas exposed to fifty 1-ms A-duration impulses at 155 dB. Note the growth of TTS between 1- to 10-h postexposure.

is a more orderly phenomenon with reduced amounts of intersubject variability.²⁷ The dynamics of the cochlear processes underlying ATS are beginning to be described.²⁸ If ATS is truly an asymptote, then it is likely that the level of ATS will represent the upper limit of PTS one can expect from prolonged exposure to the noise.

Although comparatively little data on impulse-noise-induced ATS currently exists,^{24,29,30} there appear to be differences in the manner in which ATS develops following prolonged exposures to continuous and impulse noise. From the limited data available (Fig. 3),

the following tentative conclusions can be drawn: (1) A long duration series of impulses produce a stable level of asymptotic threshold shift with prolonged exposure times. (2) For a given level of ATS, the exposure time required to reach the ATS level can be much shorter for impulse noise than for continuous noise. (3) The rate of growth to asymptote is a strong function of impulse peak level, that is, at peak levels of 99 dB, 4 to 7 days are required to reach an ATS but at peak levels of 120 dB, only 1 h is required. (4) Variations in preexposure sensitivity do not contribute to the hearing loss caused by the noise exposure. (5) The function relating impulse noise level to the level of ATS is not simple. At impulse levels below about 110 dB, ATS grows at a rate of between 0.7 and 1 dB for each decibel increase in impulse level, while above 110 dB the slope increases to between 2.6 and 5 dB of ATS per decibel increase in impulse level. The change in the slope of the ATS function may signal a transition from a primarily metabolic mode of damage to a primarily mechanical mode and may be related to the idea of a *critical intensity*.³¹⁻³³ In summary, there are significant differences between the results of ATS exposures to continuous and impulse noise.

There is extreme variability in the audiometric changes that are produced by exposure to impulse noise. For the same conditions of exposure, variability across individuals can exceed 70 dB.^{30,34} The tympanic membrane may account for part of this variability. At high levels of exposure (i.e., >160 dB for the chinchilla) the tympanic membrane (TM) can rip, which in turn leads to poorer transmission of energy through the middle ear and eventually smaller hair cell losses and less hearing loss.

There are other data³⁰ that show differences in TTS of 60 dB or more for subjects given the same exposure. Figure 3 shows individual animal data from chinchillas exposed to reverberant impulses at either 99- or 120-dB peak SPL. In the 120-dB exposure group there is a 60-dB range in the level of ATS measured at 0.5 kHz, while in the same animals tested at 8 kHz the range of the data is only about 20 dB. At the lower exposure level, one animal tested at 8 kHz did not develop ATS, while animal 1090 developed more than a 60-dB shift.

The extent of the variability in animal and controlled human studies has its parallels in demographic survey data. For example, Taylor and Pelmear,³⁵ from a carefully controlled survey in the drop forging industry, found variability so large as to preclude any meaningful description of data trends. Some typical data from the Taylor and Pelmear study illustrate the problem and are presented in Fig. 4.

5 ANATOMICAL AND PHYSIOLOGICAL CORRELATES

Hawkins³⁶ has made the case that the morphology of cochlear sensory cell lesion appears the same regardless of whether the lesion was induced by drugs, aging, or noise. However, this generalization does

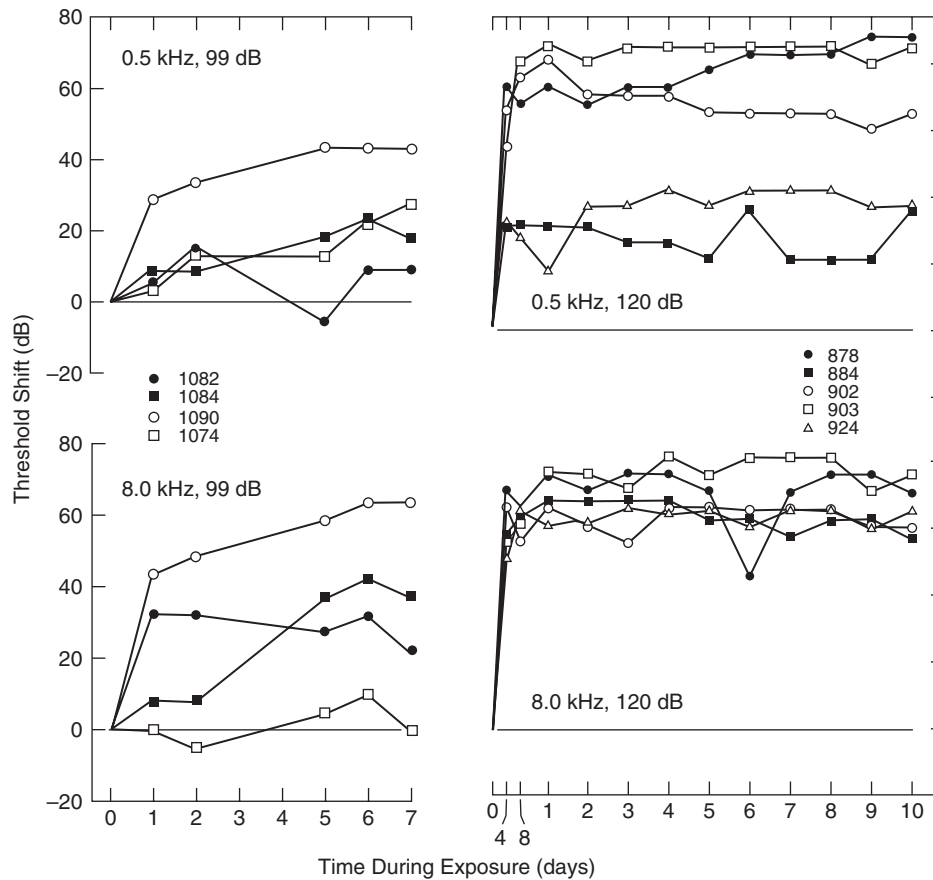

Figure 3 Asymptotic threshold shift at 0.5 kHz and 8.0 kHz in individual chinchillas exposed to two different levels of reverberant B-type impulses.³⁰

not cover some of the effects caused by impulse noise. Spoendlin³⁷ discussed the intensity levels of continuous and impulse noise required to cause direct mechanical damage to the organ of Corti and concludes that a critical level for the guinea pig for both continuous and impulse noise stimulation occurs at about 130 dB SPL. A graphic demonstration of the type of severe mechanical damage that can be seen following impulse noise exposure is shown in Fig. 5.

Figure 5 shows a scanning electron micrograph of the first turn of a chinchilla cochlea.³⁸ The animal was sacrificed within minutes of exposure. The figure illustrates the ripping of the organ of Corti from its attachments to the basilar membrane that can occur after a very brief but intense stimulation (approximately 100 impulses, at a rate of two impulses/minute at 160 dB SPL; the impulse has a 1.5-ms A duration). This type of damage is different from that observed following exposure to lower level continuous noise. This progression of changes that follow such severe mechanical damage (Fig. 5) is also probably different.³⁹ For exposure to continuous noise of a high level (above

120 dB) there are data showing "mechanically induced lesion,"⁴⁰ such as breaking of tight cell junctions, ripping of membrane, and so forth. Presumably, a severe metabolic disturbance in the cochlea results from the intermixing of perilymph and endolymph; and this disturbance to the biochemical balance leads to additional morphological changes. A similar set of conclusions was drawn by Schmeidt et al.,⁴¹ who studied the disturbance of peroxidase in guinea pig cochlea following exposure to 164-dB impulses. Some insight into the progression of damage following impulse noise exposure can be obtained from the results of Kellerhals,⁴² who exposed guinea pigs to gunfire, and Hamernik and Henderson,²⁰ who exposed guinea pigs to 50 impulses of approximately 161 dB per SPL. Both studies showed that sensory cells were lost over a period of up to 30 days.

A somewhat unusual set of result was obtained by Reinis,⁴³ who observed bleeding in the scala tympani of mice exposed to long-duration (120-ms) impulses. The occurrence of bleeding increased with peak levels of the impulse between 143 and 179 Pa

Figure 4 Age-corrected individual noise-induced permanent threshold shifts in decibels at 4 kHz for workers exposed to impulse noise in the drop forging industry.³⁵ The solid line represents the predictions of the EEH.

Figure 5 Scanning electron micrograph showing extensive tearing of the organ of Corti following blast wave exposures at 160 dB. The animal was sacrificed immediately after exposure. Outer and inner hair cells and their supporting elements (s) are torn loose from the basilar membrane. TM = tectorial membrane, H = Hensen cells. The insert shows an entire turn of the fractured organ of Corti.

(i.e., approximately 139 dB re: 20 μ Pa). Detailed histology of the cochlea was not presented.

The difference audiological and anatomical effects produced by exposure to impulse or continuous noise are primarily a function of the intensity of the noise, that is, high-level continuous noise (greater than an A-weighted sound pressure level of 120 dB) may also produce mechanical damage. However, the point of this section is that in practice it is unusual to find widespread exposures of humans to continuous noise levels in excess of 120 dB, while the contrary is true for impulse noise exposures.

6 PARAMETERS OF AN IMPULSE AND THEIR RELATIONS TO NIPTS

An understanding of the relationship between the various parameters of an impulse and the resultant noise induced permanent threshold shift (NIPTS) is essential to the development of noise standards for impulse noise exposures. In the United States, Canada, and the United Kingdom, the most accepted damage risk criteria (DRC) for impulse noise were developed in a joint effort with U.S and British scientists.² This DRC reflected a synthesis of the relatively few experimental results and observations that were available at the time. A 10-dB correction for a 100-fold change in the number of impulses was suggested and was incorporated in the Committee on Hearing and Bioacoustics (CHABA)⁴⁴ recommendations. For the purposes of this review, the Coles et al.² DRC provides a framework for organizing the results of a diverse set of experiments. The DRC developed by Smoorenburg⁴⁵ or Pfander⁸ could also serve this purpose.

The following sections review the data from various parametric studies that considered the parameters of amplitude, duration, number of impulses, repetition rates, and rise time. The insights from this review are more applicable as guidelines for research rather than data for noise standards because it is difficult to compare the results of experimental animal studies, human TTS experiments, and demographic data and arrive at definitive conclusions.

6.1 Amplitude

The peak amplitude of an impulse noise exposure is a primary consideration in many of the available damage risk criteria (DRC).^{2,8,46} However, there is not a simple relationship between the amplitude of an impulse and either cochlear damage or hearing loss.

Impulse noise experiments on human subjects using TTS are ethically limited to exposures that will produced only mild levels of TTS (i.e., 20 to 25 dB). In a systematic study by Tremolieres and Hetu⁴⁷ subjects were exposed to impact noise ranging from 107 to 137 dB. Over the 30-dB intensity range of the exposure, the average TTS increased about 15 dB or 0.5 dB per decibel of noise. Tremoliers and Hetu⁴⁷ hypothesized that the growth of TTS with exposure level was related to a power law. The Tremoliers and Hetu results build on the observation of McRobert

and Ward³³ who reported that a given impulse had a critical level, and that exposures to a few impulses above the critical level produced a considerable effect while exposure to a large number of impulses below the critical level had little effect.

Systematic data for humans are not available, but some insight can be gained from animal experiments.³⁰ Four groups of chinchillas were exposed for a week to reverberant impulses (150-ms B duration) of 99, 106, 113, or 120 dB. Figure 7 shows that the level of ATS grows considerably slower than from 113 to 120 dB. Furthermore, there was significantly more PTS and cochlear damage in the 120-dB group. The break in the function shown in Fig. 9 might reflect a change in the cochlear processes underlying noise-induced hearing loss.

There are trends in the human demographic data that parallel the rapid growth of hearing loss following exposure to impulse noise or noise environments containing impulsive components. Ceypek et al.⁴⁸ reported the permanent threshold shift of workers who developed a large hearing loss (approximately 50 dB) at 4 and 6 kHz within 1 to 2 years. The level of the loss was stable for many years and only spread to lower frequencies. Taylor and Pelmear³⁵ performed a careful demographic study of Scottish workers exposed to a combination of impact and background noise. Aside from the extreme variability, one noteworthy aspect of their results is that for a change of 20 dB in the noise exposure there is an average change of 50 dB in the observed hearing loss (Fig. 4).

Finally, when one compares two commonly cited demographic studies that relate the A-weighted sound pressure level of exposure to hearing level, for example, the data of Passchier-Vermeer⁴⁹ and Burns and Robinson,⁵⁰ the former has a considerably steeper slope and greater hearing loss for presumably the same exposure (Fig. 6). However, in the Burns and Robinson⁵⁰ data, the exposures were devoid of impulsive components, while the Passchier-Vermeer⁴⁹ results are from heterogeneous noise conditions. The data from the Taylor and Pelmear³⁵ and Kuzniarz⁵¹ studies are also plotted in Fig. 7. These studies are based on workers exposed to noise environments containing impulses; and in both cases, the Passchier-Vermeer curve is a better predictor of eventual hearing loss. Interpretation of the Ceypek et al.,⁴⁸ Taylor and Pelmear,³⁵ and Passchier-Vermeer⁴⁹ surveys is made difficult by the variability of the demographic studies, but they are in agreement with controlled laboratory experiments that show that the rate of growth of hearing loss may be accelerated when individuals are exposed to noise environments that contain impulsive noise, as compared to the acquisition of hearing loss with exposure to continuous noise alone.

6.2 Duration

The Coles et al.² DRC (Fig. 1) specifies two durations; that is, the A duration is the duration of the first overpressure in a Friedlander or blast wave, and the B duration is the time between the peak of

Figure 6 Average NIHL at 4 kHz for two populations of workers from the demographic studies of Burns and Robinson⁵⁰ and Passchier-Vermeer.⁴⁹

Figure 7 Average ATS at three test frequencies from exposure to impact noise ranging from 99 to 120 dB.³⁰

an impact and the point 20 dB down on the decay of a reverberant impulse waveform. An implicit assumption in the Coles et al.² DRC, as well as later

formulations by Pfander⁷ and Pfander et al.,⁸ is the longer duration impulses are more dangerous than the shorter duration impulses. While there is experimental support for this relationship, it is difficult to separate the importance of the impulse duration from the spectral content of an impulse. For A-type impulses, the duration is directly related to the spectrum of the impulse. Thus short-duration impulses have spectra that contain predominantly high-frequency energy and are inefficiently transmitted by the middle ear system. For longer duration impulses (1 ms), the DRC line for A-duration waves plateaus with increasing duration because the distribution of acoustic energy in the impulse is changed with the addition of lower frequencies. Price⁵² has suggested modifying the DRC to account for the resonant characteristic of the external meatus, which could enhance the transmission of an A-duration impulse in the range of 100 μ s. The B-duration criterion line continues downward because the overall energy of the impulse at audible frequencies increases in proportion to the duration of the impulse.

There are very few systematic tests of the validity of the Coles et al.² DRC, but limited data from humans and chinchillas show that the duration of an impulse is related to the traumatic effects of the exposure, and the general slope of the line seems to be reasonable. Two recent human studies support the amplitude/duration trade-off. Tremolieres and Hetu⁴⁷ exposed subjects to impact noise ranging in amplitude from 107 to 137 dB with durations of 20 to 200 ms (the duration is the time from the impulse B-weighted peak level to the 8.7 dB down point). Yamamura et al.⁵³ exposed subjects to B-type impulses of either 100 or 105 dB with B durations of either 10, 50, or 100 ms. Both of these studies limited the TTS of the subjects to low levels (approximately 20 dB), but the trend was clear; for equal amplitudes, longer duration impulses produce more TTS. These results were confirmed by Hamernik and Henderson.⁵⁴

We do not have enough data (i.e., different signatures or varied numbers) to develop an empirical relation between the number of impulses and the resulting hearing loss. None of the presently proposed DRC treats the rate of presentation, or the temporal pattern of an impulse noise exposure as a critical variable. The literature suggests two important factors that vary with time: the acoustical reflex and the rate of recovery of cochlear homeostasis following the presentation of an impulse. There results are consistent with earlier studies by Ward et al.,³² Perkins et al.,⁶ Price,⁵⁵ and Hynson.⁵

7 EQUAL ENERGY HYPOTHESIS

The equal energy hypothesis (EEH) has been expanded from the Eldred et al.⁵⁶ principal of *constant energy* and developed as a generalized scheme for evaluating most exposures where the total energy of an exposure (power \times time) is used as a predictor of hearing loss. Recently, a direct test of the EEH for impulse noise was performed using "realistic" exposures. In the first experiment,²⁴ chinchillas were exposed for 5 days

to one of four conditions: four impulses/second at 107 dB, one impulse/second at 113 dB, one impulse every four seconds at 119 dB, and one impulse every 16 seconds at 125 dB (Fig. 8).

In the second experiments (Fig. 9), chinchillas were exposed to the same class of impulse as in Fig. 8,

Figure 8 Average ATS for exposure to impulse noise (B duration = 170 ms) ranging from 107 to 125 dB SPL. The rate of presentation was varied from 4/s to 1/16s; thus each exposure has the same amount of sound energy.²⁴

Figure 9 Average maximum TTS for exposure to the same impulses as described in Fig. 8, but for these data the rate of impulse presentation was held constant and the duration of the exposure was varied to maintain equal energy.⁶¹

but the rate of presentation was held constant at one impulse/second and the duration of the exposure varied. All these exposures had the same acoustic energy but, if hearing loss was dependent on the total energy, then all groups should have the same levels of ATS. However, in both experiments there is an especially large increase in hearing loss (30 to 40 dB) when the level of noise is increased from 119 to

125 dB, and this large increment may reflect a change in the underlying mechanism of the hearing loss.

8 INTERACTION OF IMPULSE AND CONTINUOUS NOISE

Impulse/impact noise also presents a heightened risk when they occur with background noise (approximately an A-weighted sound pressure level of 85 to 95

Figure 10 (a) Group mean total number of outer hair cells (OHC) and (b) the group mean permanent threshold shift averaged at the 2.0, 4.0, and 8.0 kHz test frequencies ($\overline{PTS}_{2,4,8}$) as $\beta(t)$ is increased. \square = the broadband class of non-Gaussian noise exposures; \bullet = the standard error.

dB). Experimental studies have shown that exposure to combinations of relatively benign impact and continuous noise can lead to multiplicative interactions with hearing loss and cochlear damage with the effects of the combination exposure being greater than the simple additive effects of impulse or continuous noise.

The interaction may be a factor in demographic studies. For example, the workers in the Passchier-Vermeer study⁵⁷ had substantially more hearing loss than workers in the Burns and Robinson study,⁵⁰ who were exposed to nominally the same amount of acoustic energy. Interestingly, the subjects of Passchier-Vermeer⁵⁷ were exposed to noise that had combinations of impact and continuous noise, while the subjects of Burns and Robinson⁵⁰ were exposed to more stationary continuous noise. The enhanced danger associated with combination noise exposures may be quantified by measuring the kurtosis of a noise exposure. Lei et al.⁵⁸ have shown that the kurtotic values of a noise, as well as the energy of the exposure, are important predictors of hearing loss. Lei et al.⁵⁸ showed that non-Gaussian noise exposures would produce more trauma than energy and spectrally equivalent Gaussian exposures. The non-Gaussian character of the noise was produced by the insertion of high-level noise bursts or impact transients into the otherwise Gaussian noise. They showed that the increased trauma was related to the kurtosis, $\beta(t)$, of the non-Gaussian signal (Fig. 10). These and other animal model experiments⁵⁹ as well as industrial epidemiological data⁶⁰ suggest limitations on the use of energy-based metrics such as the L_{eq} , which are the foundation of current international standards.

In summary, exposure to certain blast and impact noise of different parameters, for example, level, duration, and temporal pattern, produces conditions of TTS and PTS that are frequently inconsistent with the EEH. However, at lower levels of exposure, there are combinations of certain parameters of impact noise that do produce results consistent with the EEH.⁶¹ Unfortunately, we simply do not have enough systematic data to delineate the range of conditions where the EEH is appropriate. For practical reasons, it is important to learn the boundary conditions of the EEH because the basic ideas behind the EEH are easy to incorporate into measurement schemes and noise standards.

CHAPTER 28

EFFECTS OF INTENSE NOISE ON PEOPLE AND HEARING LOSS

Rickie R. Davis and William J. Murphy
National Institute for Occupational Safety and Health
Cincinnati, Ohio

1 INTRODUCTION

The purpose of this chapter is to provide an overview of the effects of noise on people and their hearing. Noise is a universal problem that damages hearing and impacts quality of life. Most industrial environments have noise as a component. This chapter will provide an introduction to the functioning of the peripheral auditory system, protective mechanisms of the ear, noise damage and how it is assessed, and some discussion of how noise regulations are determined.

2 NOISE AND THE EAR

A number of works have reviewed the interaction of the ear and noise^{1,2} and other information resources such as websites (e.g., www.cdc.gov/niosh/topics/noise) are available.

Noise is most commonly defined as unwanted sound or acoustic energy. However, acoustical descriptions usually characterize noise by its intensity, its frequency spectrum, and its temporal signature. Common terms are *wideband noise*, *white noise*, *pink noise*, and *octave-band noise*.³ These terms refer to the width and shape of the frequency spectrum. Temporal signatures are *impact* and *impulse noise* and *intermittent* and *continuous noise*.

The mammalian ear is anatomically divided into three parts: the outer ear or pinna and ear canal, which ends at the *tympanic membrane* (or eardrum), the air-filled middle ear containing three bones or *ossicles*, and the inner ear or *cochlea*. The cochlea is fluid-filled and, in mammals, is shaped like a snail shell. The cochlea contains the outer and inner sensory hair cells and the basilar membrane. The outer and inner sensory hair cells differ in their shape, structural support, VIIIth nerve innervation patterns, and function. The hair cells are so-called because they have tiny structures, *stereocilia*, on their apical surface consisting of stiff actin rods that resemble hairs. The hair cells are arranged in four rows the length of the cochlea: one row of inner hair cells and three rows of outer hair cells. The stereocilia of the third row of outer hair cells are embedded in an overlying gelatinous membrane called the tectorial membrane.

Acoustical vibrations in air set the tympanic membrane into motion and the vibrations are transmitted through the middle ear bones (the ossicles). These bones serve as an impedance-matching transformer between the gas medium of the atmosphere and the liquid medium of the cochlea and provide about 30

dB of gain. These vibrations then set the fluid of the cochlea into motion. The fluid acts upon the basilar membrane and the hair cells. Low-level vibrations are enhanced through active negative damping of the outer hair cells. Vibrations are then transduced to electrochemical energy by the inner hair cells and are transmitted as action potentials via the acoustical nerve to the brain. Each inner hair cell represents a place on the basilar membrane and each place represents a particular acoustic frequency. The reader is referred to Dallos,⁴ Pickles,⁵ and other writings on the ear for a more complete exposition.

The average human cochlea is insensitive to acoustic energy below about 20 Hz and above 20 kHz. Below 20 Hz humans often feel high-level acoustic energy as whole-body vibration. Above the high-frequency limit of the human (about 20 kHz in young ears), there is usually no sensation associated with the acoustic energy.

Depending upon the frequency of the sound, the ear is capable of detecting sounds less than 0 dB SPL (sound pressure level, dB referenced to 20 μ Pa). (Often youngsters can hear certain pure tones at -10 or even -20 dB SPL in the 1 to 3 kHz frequency range.) The threshold of pain for the ear is somewhere around 130 dB. Since the decibel scale is logarithmic, this represents an extremely wide dynamic physical range of sound intensity with a ratio of quietest stimulus to the threshold of pain of more than 1 trillion.

Protective Mechanisms The cochlea can be permanently damaged by high levels of sound. The auditory periphery has several mechanisms that provide some protection against loud sounds. These mechanisms include the malleus-incus joint, the stapedal annular suspensory ligament, the middle ear muscles (or the acoustical reflex), the olivocochlear pathway, and cellular scavengers of reactive oxygen species.

The ossicles consist of the malleus (or hammer), incus (or anvil), and stapes (or stirrup) bones. The joint between the malleus and the incus is held together by a ligament. Normally this joint is tightly held together so the malleus and incus move as a unit. At very high acoustical levels this joint allows the two bones to slip against each other, reducing transmission of acoustic energy through the ossicular chain. In addition, Price⁶ has documented that the stapes bone is held against the oval window membrane of the cochlea by the annular suspensory ligament. This ligament acts as a nonlinear

spring, limiting the inward motion of the stapes and energy to the cochlea.

Located within the middle ear are two tiny muscles: the *tensor tympani* muscle is attached to the long process of the malleus and the *stapedius* muscle attached to the protuberance of the stapes—two of the bones of the ossicular transmission chain. In humans, contraction of the stapedius muscle, activated by the acoustical reflex arc, causes a stiffening of the ossicular chain transmission path and an increase in acoustic impedance. This leads to a reduction of acoustic energy presented to the cochlea. Unfortunately, the contraction requires tens of milliseconds,³⁰ adapts after a few seconds, and reduces the input by only 10 to 15 dB mainly in sounds below 1500 Hz. Thus the acoustical reflex is not a good substitute for an ear plug or muff in an industrial environment. A small percentage of the population does not exhibit an acoustical reflex.

A second reflex arc, which changes the gain of the outer hair cells, may play a protective role in the ear.⁷ The efferent olivocochlear bundle of nerve fibers originate from cell bodies in the pons of the midbrain. These efferent fibers synapse on the outer hair cells. These fibers derive their functional input from the auditory nerve. As the level of stimulation increases, the feedback to the outer hair cells changes the outer hair cell stiffness and reduces the input to the inner hair cells. In a population there are differing levels of outer hair cell drive from the olivocochlear bundle. Maison and Liberman⁸ showed in guinea pigs that those individuals possessing strong levels of olivocochlear bundle effect had decreased vulnerability to noise-induced hearing loss. Those individuals who had lower levels of olivocochlear bundle drive sustained a permanent threshold shift up to 40 dB greater than an individual with strong olivocochlear reflex drive. Normally, the olivocochlear bundle feedback functions at relatively low levels of sound producing a minor 0.5- to 1.5-dB attenuation when electrically stimulated under normal conditions. The purpose of the olivocochlear feedback loop is still controversial, and some authors argue against a protective role in high-level acoustical stimulation.⁹

The hair cells of the cochlea are prodigious consumers of oxygen. By-products of high oxygen use are the free-radical, reactive oxygen species.¹⁰ Once generated, these extremely reactive versions of oxygen immediately interact with DNA (deoxyribonucleic acid), lipids and proteins. These interactions lead to damage of cellular components. This damage can result in death of the hair cell through *apoptosis* (programmed cell death).^{11,12} Animal studies have shown that providing scavengers for free-radical oxygen species prior to and just after noise exposure can reduce the level of hearing threshold change.^{13,14} Free-radical scavengers are the local protection accorded the cochlea against insult by a high-level noise. Presently companies are marketing over-the-counter compounds for use by noise-exposed people to prevent noise-induced hearing loss. There is presently no human evidence of prophylactic effects for any compound or food supplement to prevent or reduce noise-induced

hearing loss, but this evidence may be forthcoming. In 2004 the U.S. Army funded a double-blind study in human volunteers looking for these protective effects.¹⁵

Although all of these mechanisms work in concert to reduce damage to the ear, they are inadequate for long-term protection in an industrial or military environment. Only by reducing exposure to noise can hearing be preserved.

3 AUDITORY AFTEREFFECTS OF NOISE

Figure 1 is a simple model of how the ear reacts to noise. The left-hand portion of the curve is the safe zone of the ear—noises in this range cause no measurable damage in normal people. Most people live in this range on a day-to-day basis.

Temporary threshold shift (TTS) is a change in absolute hearing threshold due to exposure to a higher level noise that resolves to *no measurable threshold shift* after some period of time. This recovery time can be from minutes to days. An intense noise exposure results in a combined threshold shift (CTS) that contains both TTS and permanent threshold shift components.

Noise of sufficient intensity and appropriate frequency can produce a permanent reduction of sensitivity of the ear to sound, also known as a *permanent threshold shift*, or *PTS*. This area of risk is represented in the right-hand portion of the curve of Fig. 1. Noise at this level can cause immediate damage to the sensory cells and supporting cells of the cochlea. This damage results in loss of outer hair cells due to *necrosis* or death due to mechanical overstimulation. Using microscopic carbon particles in chinchilla ears, Ahmad¹⁶ showed that tiny holes were developed in the reticular lamina (upper surface of the organ of Corti) of the noise-damaged cochlea. These tiny holes allowed

Figure 1 Theoretical noise damage curve. X axis is increasing sound pressure level. Y axis is increasing damage (may be shift in audiometric threshold or damage to hair cells). Left side of curve shows little or no damage due to noise. The middle section shows damage linearly increasing with noise exposure. The right section of the curve shows effect of extremely high noise exposures that asymptote with higher noise levels.

for the movement of the carbon particles from the fluid space at the tops of the hair cells to the fluid space around the hair cells. Presumably, this also allowed for the mixing of the fluids contained in these spaces (endolymph and perilymph). These fluids are very different in chemical composition and their mixing leads to death of the hair cells, or necrosis.

An intermediate level of sound can produce either TTS or PTS—the linear, central portion of Fig. 1. Currently there is little understanding of how TTS progresses to PTS or even if they are related. Detailed light and electron microscopy of the cochlea¹⁷ has found no consistent changes in either inner or outer hair cells, which correlate with the psychophysical and electrophysiological changes measured in the auditory threshold.

The regulatory community accepts that TTS is an early predictor or a process of PTS. However, TTS has proven to be a poor predictor of PTS both in animal and epidemiologic studies of humans exposed to noise.¹⁸ The underlying mechanisms for TTS and PTS are not likely the same. New techniques and research may provide a better understanding of this complex problem.

Within this linear portion of the graph (Fig. 1) the *equal-energy hypothesis (EEH)* tends to function well for continuous noise. In effect, this hypothesis says that equivalent hearing losses (generally PTS) can be produced by a low-level noise exposure over a long time and a high-level noise exposure over a short time. This hypothesis assumes that the ear integrates acoustic energy over some time period—usually 24 h. Thus, from the ear's perspective, a 1-h exposure at some sound intensity is equivalent to exposure to a sound intensity that is 3 dB less for 2 h. This is called a time–intensity trading ratio or simply trading ratio.

In the United States the linear range of this function is declared by regulations to have A-weighted sound pressure levels in the range of 90 to 120 dB. Table 1 demonstrates the difference in exposure times permitted between a 5-dB time–intensity trading ratio and a 3-dB ratio. Rather than using a physics-based 3 dB as the doubling rate, U.S. government regulators use 5 dB, under the assumption that workers will get breaks from

the noise during the day, allowing for recovery. Most countries today use a 3-dB trading ratio.

Determining the maximum acoustic energy a worker may be exposed to is a tricky political and scientific exercise. There are workers in the population so susceptible to noise that reduction of noise exposure would be economic and technologically infeasible. Subjecting normal workers to such abatement procedures would result in communication difficulties. On the other hand by setting the maximum exposure level higher indicates the amount of workers' hearing society is willing to sacrifice. Regulations are a compromise of economics, science, and politics.

The model in Fig. 1 is a reasonable first approximation for one person. However, in populations there are people for whom the entire curve may be displaced to the left (equal damage occurs at lower energy levels; labeled Sensitive in Fig. 2) or displaced to the right (exposure to higher energy levels causes less damage to the ear; labeled Resistant in Fig. 2). Currently, there is no way of predicting the sensitivity of a particular person's ears to noise. Only post hoc analysis can tell us if someone has particularly vulnerable (glass) or particularly resistant (iron) ears.

Figure 2 Three theoretical noise damage curves as in Fig. 1. The left most curve demonstrates the effects of noise on a susceptible individual. The middle curve demonstrates the effects of noise on someone with normal susceptibility to noise (most of the population). The right curve shows the effects on a person resistant to noise. On the X axis arrow 1 points to the most protective noise exposure level—virtually everyone is protected from noise-induced hearing loss. Arrow 2 points to the most economically feasible noise exposure level—at least from the noise control view. The most susceptible workers in the population would receive large hearing losses, the normal (most) workers would receive a small hearing loss and the resistant would receive little or no hearing loss. Arrow 3 points to a compromise level—some of the most susceptible individuals would still receive a hearing loss, only a small portion of the normal (most) workers would sustain a hearing loss, yet it would not require as large of investment in engineering controls or hearing conservation as level 1.

Table 1 Demonstration of Differences in Permissible Exposure Times for a 5-dB Trading Ratio versus a 3-dB Trading Ratio

Time of Permissible Unprotected Exposure ^a	5-dB Intensity/Time Trading Ratio (dB)	3-dB Intensity/Time Trading Ratio (dB)
8 h	90	90
4 h	95	93
2 h	100	96
1 h	105	99
30 min	110	102
15 min	115	105
7.5 min	120	108

^a Current U.S. OSHA regulations.

The arrows on the x axis of Fig. 2 show how difficult it is to set a noise exposure fence. A regulation designed to protect the maximum number of workers would enact the level denoted by arrow 1. Even the most susceptible workers would be protected at this level. However, this would be burdensome to employers in requiring massive layouts in noise control. It would also be burdensome to employees in that the normal or resistant workers would be overprotected. Communication and safety signal recognition may suffer. Database analyses such as the International Organization for Standardization (ISO) 1999 indicate that even at 80 dB SPL some members of a population may incur a noise-induced hearing loss. Arrow 3 denotes the most economic level. At this level society is willing to sacrifice the hearing of a small number of the normal workers and most of the susceptible workers. A compromise is denoted by arrow 2 in which the hearing of a certain proportion of the normal and susceptible population is sacrificed.

The EEH is a reasonable first approximation as long as the acoustic energy remains within the linear region of the ear. Additional assumptions are that the ear integrates the noise over a 24-h period. Schneider¹⁹ showed that the actin in the stereocilia of the hair cells is completely replaced over a 2-day period, which might indicate that sound exposure should be integrated over 2 days rather than a single 24-h day as is currently the practice. They also showed that the actin is replaced from the tip of the stereocilia rather than the base as one would guess.

Noise exposure can also result in *tinnitus*—a ringing or buzzing in the ears. Tinnitus can be thought of as the ear's pain response. Tinnitus can be present temporarily or, with continued noise exposure, it can become permanent. Current research places the generator of tinnitus in the central nervous system.²⁰ A working hypothesis is that cochlear input to the central nervous system is removed as a result of damage, and the brain produces a stimulus to replace that missing input. Generally, the subjective experience of tinnitus does not correlate with any sounds produced by the ear. Tinnitus may also be caused by exposure to chemicals (e.g., aspirin).

Susceptibility to noise-induced hearing loss is known to be specific to the individual. Workers with "tender" ears may be damaged by a particular noise while their co-workers who seem to have "tough" ears experience no damage. This effect is also seen in experimental animals. Animal research indicates that there are genetic predispositions to noise-induced hearing loss.²¹ In the human population, no specific genes have been directly linked to susceptibility to noise-induced hearing loss. However, hearing disorders such as Usher's syndrome have a genetic basis.

One of the dangers of noise is that it may mask important signals for the worker. In the previous edition of this chapter Ward²² presented a very complete discussion of masking by noise. In general terms, low-frequency noises are able to mask high-frequency noises by the "upward spread of masking." In work settings the most important signals that are masked

are co-worker speech and safety/warning signals. (The reduction of speech intelligibility by noise is complex and requires a book of its own.) The use of hearing protection and/or possession of a hearing loss, along with masking noises significantly complicates the acoustical environment and isolates the worker. Workers commonly maintain that their inability to hear speech, machinery, warning signals, and environmental sounds (e.g., "roof-talk" for underground mining) is a barrier to the use of hearing protection devices.²³ The increased masking with increasing noise level coupled with the TTS produced by noise exposure invalidates such claims. The masking by noise and the benefits of hearing protector use to reduce masking and TTS must be demonstrated to workers to overcome their reluctance to effectively use hearing protection.

4 NONAUDITORY EFFECTS—NOISE AND THE BODY

Extremely loud blasts, usually encountered only in a military setting, can produce enough acoustic energy to damage internal organs. The ear, the gastrointestinal tract, the upper respiratory tract, and the lungs are particularly susceptible to blast damage because they are air filled.²⁴ Generally, the rank order of susceptibility to damage is the ears, the lungs and the gastrointestinal tract, which is least susceptible of the three systems. Fifty percent of normal human tympanic membranes will rupture in the 57- to 345-kPa peak pressure range (190 to 200 dB SPL peak pressure).²⁵

Blast overpressure injury of the lungs can result in air emboli that can travel throughout the circulatory system. Even contusions of the lungs by blast can be life threatening. Blast overpressure lung injury may be enhanced by body armor. Foam material may more effectively couple the body to the acoustical event and increase injury.²⁶

In the civilian sector most nonauditory effects of loud noise are related to psychological stress. Noise is considered stressful if the person cannot control it nor can they habituate to it.²⁷ At low levels unsignaled noise causes an orienting response. As the level becomes louder, the person startles with an increase in blood pressure and muscular contractions. These reactions last a few seconds, with an interruption of ongoing activities. At high enough levels sleep can be compromised, impacting quality of life. With chronic exposure a stress reaction results in release of the corticosteroids, which are part of the *fight-or-flight* system.²⁷ Researchers have noted statistically significant increases in blood pressure for workers exposed to noise greater than an A-weighted sound pressure level of 75 dB.²⁸

5 RISK ANALYSIS—NOISE AND THE POPULATION

In the occupational noise setting, risk analysis attempts to determine the shape of the noise-exposure response curve for the entire worker population. If Fig. 1 is generalized to the population, the analysis attempts to

determine levels at which the population is relatively safe and how much hearing damage will be produced at various levels of noise exposure. Due to individual susceptibility to noise and the inconsistent use of hearing protection, this is never a straightforward exercise. Risk analysis is very important for setting government regulations and can have significant impact on costs associated with protecting workers. In order to protect the most susceptible segment of the population, costs of hearing loss prevention programs may be doubled or tripled.

Risk analysis of occupational hearing loss is an important field of study and readers are referred to Prince²⁹ as a starting point.

CHAPTER 29

EFFECTS OF VIBRATION ON PEOPLE

Michael J. Griffin
Human Factors Research Unit
Institute of Sound and Vibration Research
University of Southampton
Southampton, United Kingdom

1 INTRODUCTION

Human responses to vibration determine the acceptability of vibration in many environments. There are three categories of human exposure:

Whole-Body Vibration Where the body is supported on a vibrating surface (e.g., sitting on a seat that vibrates, standing on a vibrating floor, or lying on a vibrating surface).

Motion Sickness Caused by real or illusory movements of the body or the environment at low frequency (usually less than 1 Hz).

Hand-Transmitted Vibration Caused by processes in industry, agriculture, mining, construction, and transport where vibrating tools or workpieces are grasped or pushed by the hands or fingers.

This chapter identifies the principal human responses to vibration, summarizes methods of measuring, evaluating, and assessing exposures to vibration, and minimizing effects of vibration.

The vibration to which the human body is exposed is usually measured with accelerometers and expressed in terms of the acceleration, in metres per second per second (i.e., m s^{-2} , or m/s^2). The vibration is measured at the interface between the body and the surface in contact with the body (e.g., on the seat beneath the ischial tuberosities for a seated person; on a handle held by the hand).

Some human responses to vibration depend on the duration of exposure. The duration of measurement of vibration may affect the measured magnitude of the vibration when the conditions are not statistically stationary. The root-mean-square (rms) acceleration is often used, but it may not provide a good indication of vibration severity if the vibration is intermittent, contains shocks, or otherwise varies in magnitude from time to time.

The responses of the body differ according to the direction of the motion (i.e., axes of vibration). The three directions of whole-body vibration for seated and standing persons are fore and aft (x axis), lateral (y axis), and vertical (z axis). Figure 1 illustrates the translational and rotational axes for a seated person and the axes of hand-transmitted vibration.

Figure 1 Axes of vibration used to measure exposures to (a) whole-body vibration and (b) hand-transmitted vibration.

2 WHOLE-BODY VIBRATION

Vibration of the whole body is produced by transport (road, off-road, rail, sea, and air), by some industrial machinery, and occurs in buildings. Whole-body vibration can affect human comfort as well as the performance of activities and health. An understanding of these effects and means of minimizing unwanted effects can be assisted by knowledge of the biodynamics of the body.

2.1 Biodynamics

The human body is a complex mechanical system that does not, in general, respond to vibration in the same manner as a rigid mass: There are relative motions between the body parts that vary with the frequency and the direction of the applied vibration. The dynamics of the body affect all human responses to vibration. However, the discomfort, the interference with activities, and the health effects of vibration cannot be predicted solely by considering the body as a mechanical system.

2.1.1 Transmissibility of the Human Body The resonances of the body vary with the direction of excitation, where the vibration is measured, as well as the posture of the body and the individual. For seated persons, there are resonances to the head at frequencies in the range 4 to 12 Hz for vertical vibration below 4 Hz with *x*-axis vibration, and below 2 Hz with lateral vibration.^{1,2} A seat back can alter the transmission of vibration to the head and upper body of seated people, and bending of the legs affects the transmission of vibration to standing persons.

2.1.2 Mechanical Impedance of the Human Body Point mechanical impedance of the seated human shows a principal resonance for vertical vibration at about 5 Hz and, sometimes, a second resonance in the range 7 to 12 Hz.³ This response means the body cannot usually be represented by a rigid mass when measuring (or predicting) the vibration transmitted through seats. The mechanical impedance of the body is generally nonlinear: The resonance frequency reduces when the vibration magnitude increases.

2.1.3 Biodynamic Models A simple model with one or two degrees of freedom can represent the point mechanical impedance of the body, and dummies may be constructed to represent this impedance for seat testing. The transmissibility of the body is affected by many more variables and requires more complex models reflecting the posture of the body and the translation and rotation associated with the various modes of vibration.

2.2 Vibration Discomfort

Vibration discomfort depends on various factors in addition to the characteristics of the vibration. It is often sufficient to predict the relative discomfort of different motions and not necessary to predict the absolute acceptability of vibration.

2.2.1 Vibration Magnitude The absolute threshold for the perception of vertical whole-body vibration in the frequency range of 1 to 100 Hz is, very approximately, 0.01 m s^{-2} rms; a magnitude of 0.1 m s^{-2} will be easily noticeable; magnitudes around 1 m s^{-2} rms are usually considered uncomfortable; magnitudes of 10 m s^{-2} rms are usually dangerous. The precise values depend on vibration frequency and the exposure duration, and they are different for other axes of vibration.

For some common motions, doubling the vibration magnitude approximately doubles the sensation of discomfort.⁴ Halving a vibration magnitude can therefore produce a considerable reduction in discomfort. For some motions, the smallest detectable change in vibration magnitude (the difference threshold) is about 10%.⁵

2.2.2 Effects of Vibration Frequency and Direction Frequency weightings take account of the different sensitivity of the body to different frequencies. British Standard 6841⁶ and International Standard 2631⁷ define similar procedures for predicting vibration discomfort. Figure 2 shows frequency weightings W_b to W_f as defined in British Standard 6841; International Standard 2631 suggests the use of W_k in place of the almost identical weighting W_b . Table 1 shows how the weightings should be applied to the 12 axes of vibration illustrated in Fig. 1a. The weightings W_g and W_f are not required to predict vibration discomfort: W_g has been used for assessing interference with activities and is similar to the weighting for vertical vibration in ISO 2631⁸; W_f is used to predict motion sickness caused by vertical oscillation.

Some frequency weightings are used for more than one axis of vibration, with different *multiplying factors* allowing for overall differences in sensitivity between axes (Table 1). The frequency-weighted acceleration should be multiplied by the multiplying factor before the component is compared with components in other axes, or included in any summation over axes. The rms value of this acceleration (i.e., after

Figure 2 Acceleration frequency weightings for whole-body vibration and motion sickness as defined in BS 6841⁶ and ISO 2631.⁷

Table 1 Application of Frequency Weightings for the Evaluation of Vibration with Respect to Discomfort

Input Position	Axis	Frequency Weighting	Axis Multiplying Factor
Seat	x	W_d	1.0
	y	W_d	1.0
	z	W_b	1.0
	r_x (roll)	W_e	0.63
	r_y (pitch)	W_e	0.40
Seat back	r_z (yaw)	W_e	0.20
	x	W_c	0.80
	y	W_d	0.50
	z	W_d	0.40
Feet	x	W_b	0.25
	y	W_b	0.25
	z	W_b	0.40

frequency weighting and after being multiplied by the multiplying factor) is called a *component ride value*. In order to obtain an *overall ride value*, the *root-sums-of-squares* of the component ride values is calculated:

$$\text{Overall ride value} = \left[\sum (\text{component ride values})^2 \right]^{1/2}$$

Overall ride values from different environments can be compared with each other, and overall ride values can be compared with Fig. 3 showing the ranges of vibration magnitudes associated with varying degrees of discomfort.

2.2.3 Effects of Vibration Duration The rate of increase in discomfort with increase in vibration duration may depend on many factors, but a simple fourth-power time dependency is used to approximate the change from the shortest possible shock to a

**Figure 3** Scale of vibration discomfort from British Standard 6841⁶ and International Standard 2631.⁷**Table 2 Vibration Dose Values at Which Various Degrees of Adverse Comment May Be Expected in Buildings**

Place	Low Probability of Adverse Comment	Adverse Comment Possible	Adverse Comment Probable
Critical working areas	0.1	0.2	0.4
Residential	0.2–0.4	0.4–0.8	0.8–1.6
Office	0.4	0.8	1.6
Workshops	0.8	1.6	3.2

Source: Based on International Standard 2631 Part 2 (1989) and British Standard 6472 (1992)^{4,9,10}

full day of vibration exposure [i.e., (acceleration)⁴ × duration = constant, see Section 2.4.2].

2.2.4 Vibration in Buildings Acceptable magnitudes of vibration in some buildings are close to vibration perception thresholds. The acceptability of vibration in buildings depends on the use of the building in addition to the vibration frequency, direction, and duration. Using the guidance in ISO 2631 Part 2,⁹ it is possible to summarize the acceptability of vibration in different types of buildings in a single table of vibration dose values (see BS 6472; Table 2¹⁰). The vibration dose values in Table 2 are applicable irrespective of whether the vibration occurs as a continuous vibration, intermittent vibration, or repeated shocks.

2.3 Interference with Activities

Vibration can interfere with the acquisition of information (e.g., by the eyes), the output of information (e.g., by hand or foot movements), or the complex central processes that relate input to output (e.g., learning, memory, decision making).

2.3.1 Effects of Vibration on Vision Reading a book or newspaper in a vehicle may be difficult because the paper is moving, the eye is moving, or both the paper and the eye are moving. There are many variables affecting visual performance in these conditions: It is not possible to adequately represent the effects of vibration on vision without considering the effects of these variables.⁴

2.3.2 Manual Control Writing and other complex control tasks involving hand control activities can also be impeded by vibration. The characteristics of the task and the characteristics of the vibration combine to determine effects of vibration on performance: A given vibration may greatly affect one type of control task but have little affect on another. The effects of vertical whole-body-vibration on spilling liquid from a hand-held cup are often greatest close to 4 Hz; the effects of vibration on writing speed and writing difficulty are most affected by vertical vibration in the range 4 to 8 Hz.¹¹ Although 4 Hz is a sensitive frequency for both drinking and the writing tasks, the dependence on

frequency of the effects of vibration are different for the two activities.

International Standard 2631 offered a *fatigue-decreased proficiency* boundary as a means of predicting the effects of vibration on activities.⁸ A complex time-dependent magnitude of vibration was said to be “a limit beyond which exposure to vibration can be regarded as carrying a significant risk of impaired working efficiency in many kinds of tasks, particularly those in which time-dependent effects (“fatigue”) are known to worsen performance as, for example, in vehicle driving.” Vibration may influence “fatigue,” but there is, as yet, little evidence justifying the complex fatigue-decreased proficiency boundary presented in this standard.

2.3.3 Cognitive Performance Simple cognitive tasks (e.g., simple reaction time) appear to be unaffected by vibration, other than by changes in arousal or motivation or by direct effects on input and output processes. This may also be true for some complex cognitive tasks. However, the scarcity of experimental studies and the diversity of findings allows the possibility of real and significant cognitive effects of vibration.

2.4 Health Effects

Disorders have been reported among persons exposed to vibration in occupational, sport, and leisure activities. The studies do not agree on the type or the extent of disorders, and the findings have not always been related to appropriate measurements of vibration exposure. However, it is often assumed that disorders of the back (back pain, displacement of intervertebral disks, degeneration of spinal vertebrae, osteoarthritis, etc.) may be associated with vibration exposure.^{4,12} There may be several alternative causes of any increase in disorders of the back among persons exposed to vibration (e.g., poor sitting postures, heavy lifting). It is often not possible to conclude confidently that a back disorder is solely, or primarily, caused by vibration.¹³

2.4.1 Evaluation of Whole-Body Vibration The manner in which the health effects of oscillatory motions depend upon the frequency, direction, and duration of motion is currently assumed to be similar to that for vibration discomfort. However, it is assumed that the *total* exposure, rather than the *average* exposure, is important.

2.4.2 Assessment of Whole-Body Vibration British Standard 6841⁶ and International Standard 2631⁷ give guidance on the severity of exposures to whole-body vibration. There are similarities between the two standards, but the methods within ISO 2631 are internally inconsistent.¹⁴

British Standard 6841 British Standard 6841 defines an *action level* for vertical vibration based *vibration dose values*.⁶ The vibration dose value uses a *fourth-power* time dependency to accumulate vibration

severity over the exposure period from the shortest possible shock to a full day of vibration:

$$\text{Vibration dose value} = \left[\int_{t=0}^{t=T} a^4(t) dt \right]^{1/4}$$

where $a(t)$ is the frequency-weighted acceleration. If the exposure duration (t , seconds) and the frequency-weighted rms acceleration (a_{rms} , m s^{-2} rms) are known for conditions in which the vibration characteristics are statistically stationary, it can be useful to calculate the *estimated vibration dose value*, eVDV:

$$\text{Estimated vibration dose value} = 1.4a_{\text{rms}}t^{1/4}$$

The eVDV is not applicable to transients, shocks, and repeated shock motions in which the crest factor (peak value divided by the rms value) is high.

No precise limit can be offered to prevent disorders caused by whole-body vibration, but British Standard 6841⁶ (p. 18) offers the following guidance:

High vibration dose values will cause severe discomfort, pain and injury. Vibration dose values also indicate, in a general way, the severity of the vibration exposures which caused them. However there is currently no consensus of opinion on the precise relation between vibration dose values and the risk of injury. It is known that vibration magnitudes and durations which produce vibration dose values in the region of $15 \text{ m s}^{-1.75}$ will usually cause severe discomfort. It is reasonable to assume that increased exposure to vibration will be accompanied by increased risk of injury (p. 18).

An action level might be set higher or lower than $15 \text{ m s}^{-1.75}$. Figure 4 shows this action level for exposure durations from one second to one day.

International Standard 2631 International Standard 2631⁷ offers two different methods of evaluating vibration severity with respect to health effects, and for both methods there are two boundaries. When evaluating vibration using the vibration dose value, it is suggested that below a boundary corresponding to a vibration dose value of $8.5 \text{ m s}^{-1.75}$ “health risks have not been objectively observed,” between 8.5 and $17 \text{ m s}^{-1.75}$ “caution with respect to health risks is indicated,” and above $17 \text{ m s}^{-1.75}$ “health risks are likely.” The two boundaries define a *VDV health guidance caution zone*. The alternative method of evaluation in ISO 2631 uses a time dependency in which the acceptable vibration does not vary with duration between 1 and 10 min and then decreases in inverse proportion to the square root of duration from 10 min to 24 h. This method suggests an *rms health guidance caution zone*, but the method is not fully defined in the text, it allows very high accelerations at short durations, it conflicts with the vibration dose

Figure 4 Comparison between the health guidance caution zones for whole-body vibration in ISO 2631-1 (1997) (3 to $6 \text{ m s}^{-2} \text{ rms}$; 8.5 to $17 \text{ m s}^{-1.75}$), $15 \text{ m s}^{-1.75}$ action level implied in BS 6841 (1987), the exposure limit values and exposure action values for whole-body vibration in the EU Physical Agents (Vibration) Directive.^{6,7,15}

value method and cannot be extended to exposure durations below 1 min (Fig. 4).

With severe vibration exposures, prior consideration of the fitness of the exposed persons and the design of adequate safety precautions may be required. The need for regular checks on the health of routinely exposed persons may also be considered.

2.4.3 EU Machinery Safety Directive The Machinery Safety Directive of the European Community (89/392/EEC) states that machinery must be designed and constructed so that hazards resulting from vibration produced by the machinery are reduced to the lowest practicable level, taking into account technical progress and the availability of means of reducing vibration.¹⁶ The instruction handbooks for machinery causing whole-body vibration must specify the equivalent acceleration to which the body is exposed where this exceeds some stated value (for whole-body vibration this is currently a frequency-weighted acceleration of $0.5 \text{ m s}^{-2} \text{ rms}$). The relevance of any such value will depend on the test conditions to be specified in other standards. Many work vehicles exceed this value at some stage during an operation or journey. Standardized procedures for testing work vehicles are being prepared; the values currently quoted by manufacturers may not always be representative of the operating conditions in the work for which the machinery is used.

2.4.4 EU Physical Agents Directive (2002) In 2002, the Parliament and Commission of the European Community agreed on "minimum health and safety requirements" for the exposure of workers to the risks

arising from vibration.¹⁵ For whole-body vibration, the directive defines an 8-h equivalent *exposure action value* of $0.5 \text{ m s}^{-2} \text{ rms}$ (or a vibration dose value of $9.1 \text{ m s}^{-1.75}$) and an 8-h equivalent *exposure limit value* of $1.15 \text{ m s}^{-2} \text{ rms}$ (or a vibration dose value of $21 \text{ m s}^{-1.75}$). Member states of the European Union were required to bring into force laws to comply with the directive by 6 July 2005.

The directive says that workers shall not be exposed above the exposure limit value. If the exposure action values are exceeded, the employer shall establish and implement a program of technical and/or organizational measures intended to reduce to a minimum exposure to mechanical vibration and the attendant risks. The directive says workers exposed to vibration in excess of the exposure action values shall be entitled to appropriate health surveillance. Health surveillance is also required if there is any reason to suspect that workers may be injured by the vibration even if the exposure action value is not exceeded.

The probability of injury arising from occupational exposures to whole-body vibration at the exposure action value and the exposure limit value cannot be estimated because epidemiological studies have not yet produced dose-response relationships. However, it seems clear that the Directive does not define *safe exposures* to whole-body vibration since the rms values are associated with extraordinarily high magnitudes of vibration (and shock) when the exposures are short: These exposures may be assumed to be hazardous (see Fig. 4¹⁷). The vibration dose value procedure

suggests more reasonable vibration magnitudes for short-duration exposures.

2.5 Seating Dynamics

Seating dynamics can greatly influence the vibration responsible for discomfort, interference with activities, and injury. Most seats exhibit a resonance at low frequencies resulting in higher magnitudes of vertical vibration occurring on the seat than on the floor. At high frequencies, there is usually attenuation of vertical vibration. The principal resonance frequencies of common vehicle seats are usually in the region of 4 Hz. The variations in transmissibility between seats are sufficient to result in significant differences in the vibration experienced by people supported by different seats.

The transmissibility of a seat is dependent on the mechanical impedance of the human body, so the transmissibility of a seat measured with a mass supported on the seat will be different from that with a human body sitting in the seat. The nonlinearity of the body mechanical impedance results in seat transmissibilities that vary with changes in vibration magnitude and vibration spectra entering the seat. Measurements of seat transmissibility can be undertaken on laboratory simulators with volunteer subjects, but safety and ethical precautions are required to protect subjects.¹⁸ Measurements may also be performed in vehicles. Anthropodynamic dummies are being developed to represent the average mechanical impedance of the human body so that laboratory and field studies can be performed without exposing people to vibration. Seat transmissibility may be predicted from the dynamic stiffness of a seat and the apparent mass of the human body.

The suitability of a seat for a specific vibration environment depends on: (1) the vibration spectra present in the environment, (2) the transmissibility of the seat, and (3) the sensitivity of the human body to the different frequencies of vibration. These three functions of frequency are contained within a simple numerical indication of the isolation efficiency of a seat called the *seat effective amplitude transmissibility* (SEAT).⁴ In concept, the SEAT value compares the vibration severity on a seat with the vibration severity on the floor beneath the seat:

$$\text{SEAT}(\%) = \frac{\text{ride comfort on seat}}{\text{ride comfort on floor}} \times 100$$

A SEAT value greater than 100% indicates that, overall, the vibration on the seat is *worse* than the vibration on the floor beneath the seat; SEAT values below 100% indicate that the seat has provided some useful attenuation. Seats should be designed to have the lowest SEAT value compatible with other constraints. In common cars, SEAT values are often in the range of 60 to 80%. In railway carriages the SEAT value for vertical vibration is likely to be greater than 100% because conventional seats cannot provide any attenuation of the low-frequency vibration that is normally present in such vehicles. The optimization of

the seating dynamics can be the most effective method of improving vehicle ride.

The SEAT value may be calculated from either the frequency-weighted rms values (if the vibration does not contain transients) or the vibration dose values of the frequency-weighted acceleration on the seat and the floor:

$$\text{SEAT}(\%) = \frac{\text{vibration dose value on seat}}{\text{vibration dose value on floor}} \times 100$$

The SEAT value is influenced by the vibration input and not merely by the dynamics of the seat: Different values are obtained with the same seat in different vehicles. The SEAT value indicates the suitability of a seat for attenuating a particular type of vibration.

Conventional seating (comprising some combination of foam, rubber, or metal springing) usually has a resonance at about 4 Hz and, therefore, provides no attenuation at frequencies below about 6 Hz. Attenuation can be provided at frequencies down to about 2 or 3 Hz using a separate suspension mechanism beneath the seat pan. In such suspension seats, used in some off-road vehicles, trucks, and coaches, there are low-resonance frequencies (often below about 2 Hz). This is beneficial if the dominant vibration is at higher frequencies, but of no value if the dominant motion is at very low frequencies. Standards for testing the suitability of suspension seats for specific classes of work vehicles have been prepared (see International Standards ISO 5007,¹⁹ ISO 7096,²⁰ and ISO 10326-1²¹). The suspension mechanism (comprising a spring and damper mechanism) has a limited travel, often 50 to 100 mm. If the relative motion of the suspension reaches this limit, there will be an impact that might cause more discomfort or hazard than would have been present with a conventional seat. Suspension seats are nonlinear (having friction affecting response with low magnitude motions, and hitting end-stops with high magnitudes), and their full response requires consideration of the dynamic response of the cushion and the impedance of the human body in addition to the idealized response of the damper and spring.

3 MOTION SICKNESS

Illness (e.g., vomiting, nausea, sweating, color changes, dizziness, headaches, and drowsiness) is a normal response to motion in fit and healthy people. Translational and rotational oscillation, constant speed rotation about an off-vertical axis, Coriolis stimulation, movements of the visual scene, and various other stimuli producing sensations associated with movement of the body can cause sickness.²² However, motion sickness is neither explained nor predicted solely by the physical characteristics of motion.

Motion sickness arises from motions at frequencies associated with normal postural control of the body, usually less than 1 Hz. Laboratory studies with vertical oscillation and studies of motion sickness in ships led to the formulation of a frequency weighting,

W_f (Fig. 2), and the *motion sickness dose value* for predicting sickness caused by vertical oscillation:

$$\text{Motion sickness dose value (MSDV)} = a_{\text{rms}} t^{1/2}$$

where a_{rms} is the root-mean-square value of the frequency-weighted acceleration (m s^{-2}) and t is the exposure period (seconds).^{6,7,23} The percentage of unadapted adults who are expected to vomit is given by $1/3$ MSDV. These relationships have been derived from exposures in which up to 70% of persons vomited during exposures lasting between 20 min and 6 h.

Vertical oscillation is not the principal cause of sickness in road vehicles or trains, so the above expression should not be assumed to be applicable to the prediction of sickness in all environments.

4 HAND-TRANSMITTED VIBRATION

Exposure of the fingers or the hands to vibration or repeated shock can give rise to various signs and symptoms. Five types of disorder may be identified: (1) circulatory disorders, (2) bone and joint disorders, (3) neurological disorders, (4) muscle disorders, and (5) other general disorders (e.g., central nervous system).⁴ More than one disorder can affect a person at the same time, and it is possible that the presence of one disorder facilitates the appearance of another. The onset of each disorder is dependent on the vibration characteristics, individual susceptibility to damage, and other aspects of the environment. The term *hand-arm vibration syndrome* (HAVS) is sometimes used to refer to an unspecified combination of one or more of the disorders.

4.1 Sources of Hand-Transmitted Vibration

The vibration on tools varies greatly depending on tool design and method of use, so it is not possible to categorize individual tool types as *safe* or *dangerous*. Table 3 lists some tools and processes that are common causes of vibration-induced injury.

4.2 Effects of Hand-Transmitted Vibration

4.2.1 Vascular Disorders Vibration-induced white finger (VWF) is characterized by intermittent whitening (i.e., blanching) of the fingers. The fingertips are usually the first to blanch, but the affected area may extend to all of one or more fingers with continued vibration exposure. Attacks of blanching are precipitated by cold and therefore often occur in cold conditions or after contact with cold objects. The blanching lasts until the fingers are rewarmed and vasodilation allows the return of the blood circulation. Many years of vibration exposure often occur before the first attack of blanching is noticed. Affected persons often have other signs and symptoms, such as numbness and tingling. Cyanosis and, rarely, gangrene, have also been reported.

The severity of the effects of vibration are recorded by reference to the *stage* of the disorder. The staging of vibration-induced white finger is based on verbal

Table 3 Tools and Processes Potentially Associated with Vibration Injuries^a

Category of Tool	Examples of Tool
Percussive metal-working tools	Powered percussive metal-working tools, including powered hammers for riveting, caulking, hammering, clinching, and flanging. Hammer swaging.
Percussive tools used in stone working, quarrying, construction, etc.	Percussive hammers, vibratory compactors, concrete breakers, pokers, sanders, and drills used in mining, quarrying, demolition, and road construction.
Grinders and other rotary tools	Pedestal grinders, hand-held portable grinders, flex-driven grinders and polishers, and rotary burring tools.
Timber and woodworking machining tools	Chain saws, brush cutters (clearing saws), hand-held or hand-fed circular saws, electrical screwdrivers, mowers and shears, hardwood cutting machines, barking machines, and strimmers.
Other processes and tools	Pounding machines used in shoe manufacture, drain suction machines, nut runners, concrete vibro-thickeners, and concrete levelling vibro-tables.

^a The Health and Safety Executive suggest that for all workers using these vibratory tools health surveillance is likely to be appropriate.

Source: From Health and Safety Executive, 1994.²⁴

statements made by the affected person. In the Stockholm workshop staging system, the staging is influenced by the frequency of attacks of blanching and the areas of the digits affected by blanching (Table 4).

A *scoring system* is used to record the areas of the digits affected by blanching (Fig. 5).⁴ The scores correspond to areas of blanching on the digits commencing with the thumb. On the fingers a score of 1 is given for blanching on the distal phalanx, a score of 2 for blanching on the middle phalanx, and a score of 3 for blanching on the proximal phalanx. On the thumbs the scores are 4 for the distal phalanx and 5 for the proximal phalanx. The blanching scores for each finger, which are formed from the sums of the scores on each phalanx, may be based on statements from the affected person or on the visual observations of a designated observer.

4.2.2 Neurological Disorders Numbness, tingling, elevated sensory thresholds for touch, vibration, temperature, and pain, and reduced nerve conduction velocity are now considered to be separate effects of vibration and not merely symptoms of vibration-induced white finger. A method of reporting the extent of vibration-induced neurological effects of vibration

Table 4 Stockholm Workshop Scale for Classification of Vibration-Induced White Finger^a

Stage	Grade	Description
0	—	No attacks
1	Mild	Occasional attacks affecting only the tips of one or more fingers
2	Moderate	Occasional attacks affecting distal and middle (rarely also proximal) phalanges of one or more fingers
3	Severe	Frequent attacks affecting all phalanges of most fingers
4	Very severe	As in stage 3, with trophic skin changes in the finger tips

^a If a person has stage 2 in two fingers of the left hand and stage 1 in a finger on right hand, the condition may be reported as 2L(2)/1R(1). There is no defined means of reporting the condition of digits when this varies between digits on the same hand. The scoring system is more helpful when the extent of blanching is to be recorded.

Source: From Ref.²⁵

Table 5 Proposed Sensorineural Stages of the Effects of Hand-Transmitted Vibration

Stage	Symptoms
0 _{SN}	Exposed to vibration but no symptoms
1 _{SN}	Intermittent numbness with or without tingling
2 _{SN}	Intermittent or persistent numbness, reduced sensory perception
3 _{SN}	Intermittent or persistent numbness, reduced tactile discrimination and/or manipulative dexterity

Source: From Ref. 26.

has been proposed (see Table 5). This staging is not currently related to the results of any specific objective test: The *sensorineural stage* is a subjective impression of a physician based on the statements of the affected person or the results of any available clinical or scientific testing. Neurological disorders are sometimes identified by screening tests using measures of sensory function, such as the thresholds for feeling vibration, heat, or warmth on the fingers.

4.2.3 Muscular Effects Workers exposed to hand-transmitted vibration sometimes report difficulty with their grip, including reduced dexterity, reduced grip strength, and locked grip. Many of the reports are derived from symptoms reported by exposed persons, rather than signs detected by physicians, and could be a reflection of neurological problems. Muscle activity may be of great importance to tool users since a secure grip can be essential to the performance of the job and the safe control of the tool. The presence of vibration on a handle may encourage the adoption of a tighter grip than would otherwise occur; a tight grip may also increase the transmission of vibration to the hand and reduce the blood flow within the fingers. If the chronic

Figure 5 Method of scoring the areas of the digits affected by blanching.⁴ The blanching scores for the hands shown are 01300_{right} and 01366_{left}.

effects of vibration result in reduced grip, this may help to protect operators from further effects of vibration but interfere with both work and leisure activities.

4.2.4 Articular Disorders Surveys of the users of hand-held tools have found evidence of bone and joint problems, most often among men operating percussive tools such as those used in metal-working jobs and mining and quarrying. It is speculated that some characteristic of such tools, possibly the low-frequency shocks, is responsible. Some of the reported injuries relate to specific bones and suggest the existence of cysts, vacuoles, decalcification, or other osteolysis, degeneration, or deformity of the carpal, metacarpal, or phalangeal bones. Osteoarthritis and olecranon spurs at the elbow and other problems at the wrist and shoulder are also documented.⁴ There is not universal acceptance that vibration is the cause of articular problems, and there is currently no dose–effect relation predicting their occurrence. In the absence of specific information, it seems that adherence to current guidance for the prevention of vibration-induced white finger may provide reasonable protection.

4.2.5 Other Effects Hand-transmitted vibration may not only affect the fingers, hands, and arms: Studies have reported an increased incidence of problems such as headaches and sleeplessness among tool users and have concluded that these symptoms are caused by hand-transmitted vibration. Although these are real problems to those affected, they are “subjective” effects that are not accepted as real by all researchers. Some current research is seeking a physiological basis for such symptoms. It would appear that caution is appropriate, but the adoption of modern guidance to prevent vibration-induced white finger may also provide some protection from any other effects of hand-transmitted vibration within, or distant from, the hand.

4.3 Standards for the Evaluation of Hand-Transmitted Vibration

There are various standards for the measurement, evaluation, and assessment of hand-transmitted vibration.

4.3.1 Vibration Measurement International Standards 5349-1²⁷ and 5349-2²⁸ give recommendations on methods of measuring the hand-transmitted vibration on tools and processes. Guidance on vibration measurements on specific tools is given elsewhere (e.g., ISO 8662).²⁹ Care is required to obtain representative measurements of tool vibration with appropriate operating conditions. There can be difficulties in obtaining valid measurements using some commercial instrumentation (especially when there are high shock levels). It is wise to determine acceleration spectra and inspect the acceleration time histories before accepting the validity of any measurements.

4.3.2 Vibration Evaluation All current national and international standards use the same frequency weighting (called W_h) to evaluate hand-transmitted vibration over the approximate frequency range of 8 to 1000 Hz (Fig. 6).³⁰ This weighting is applied to measurements of vibration acceleration in each of the three axes of vibration at the point of entry of vibration to the hand. More recent standards suggest the overall severity of hand-transmitted vibration should be calculated from root-sums-of-squares of the frequency-weighted acceleration in the three axes. The standards imply that if two tools expose the hand to vibration for the same period of time, the tool having the lowest frequency-weighted acceleration will be least likely to cause injury or disease.

Occupational exposures to hand-transmitted vibration can have widely varying daily exposure durations—from a few seconds to many hours. Often, exposures are intermittent. To enable a daily exposure to be reported simply, the standards refer to an equivalent 8-h exposure:

$$a_{hw(eq,8h)} = A(8) = a_{hw} \left[\frac{t}{T_{(8)}} \right]^{1/2}$$

where t is the exposure duration to an rms frequency-weighted acceleration, a_{hw} , and $T_{(8)}$ is 8 h (in the same units as t).

4.3.3 Vibration Assessment According to ISO 5349 In an informative annex of ISO 5349-1²⁷ there is a suggested relation between the lifetime

Figure 6 Frequency weighting W_h for the evaluation of hand-transmitted vibration.

Figure 7 Relation between daily $A(8)$ and years of exposure expected to result in 10% incidence of finger blanching according to ISO 5349 (2001). A 10% probability of finger blanching is predicted after 12 years at the EU exposure action value and after 5.8 years at the EU exposure limit value.^{15,27}

exposure to hand-transmitted vibration, D_y (in years), and the 8-h energy-equivalent daily exposure $A(8)$ for the conditions expected to cause 10% prevalence of finger blanching (Fig. 7):

$$D_y = 31.8[A(8)]^{-1.06}$$

The percentage of affected persons in any group of exposed persons will not always correspond to the values shown in Fig. 7: The frequency weighting, the time dependency, and the dose–effect information are based on less than complete information, and they have been simplified for practical convenience. Additionally, the number of persons affected by vibration will depend on the rate at which persons enter and leave the exposed group. The complexity of the above equation implies far greater precision than is possible: A more convenient estimate of the years of exposure (in the range 1 to 25 years) required for 10% incidence of finger blanching is

$$D_y = \frac{30.0}{A(8)}$$

This equation gives the same result as the equation in the standard (to within 14%), and there is no information suggesting it is less accurate.

The informative annex to ISO 5349 (2001, Ref. 27, pp. 15–17) states: “Studies suggest that symptoms of the hand-arm vibration syndrome are rare in persons exposed with an 8-h energy-equivalent vibration total value, $A(8)$, at a surface in contact with the hand, of less than 2 m/s² and unreported for $A(8)$ values less than 1 m/s².” However, this sentence should be interpreted with caution in view of the very considerable doubts over the frequency weighting and time dependency in the standard.³¹

4.3.4 EU Machinery Safety Directive The Machinery Safety Directive of the European Community (89/392/EEC) requires that instruction handbooks for hand-held and hand-guided machinery specify the equivalent acceleration to which the hands or arms are subjected where this exceeds a stated value (currently a frequency-weighted acceleration of $2.5 \text{ m s}^{-2} \text{ rms}$).¹⁶ Very many hand-held vibrating tools can exceed this value. Standards defining test conditions for the measurement of vibration on many tools (e.g., chipping and riveting hammers, rotary hammers and rock drills, grinding machines, pavement breakers, chain saws) have been defined (e.g., ISO 8662²⁹).

4.3.5 EU Physical Agents Directive (2002) For hand-transmitted vibration, the EU Physical Agents Directive defines an 8-h equivalent exposure action value of $2.5 \text{ m s}^{-2} \text{ rms}$ and an 8-h equivalent, exposure limit value of $5.0 \text{ m s}^{-2} \text{ rms}$ (Fig. 8).¹⁵ The directive says workers shall not be exposed above the exposure limit value. If the 'exposure action values are exceeded, the employer shall establish and implement a program of technical and/or organizational measures intended to reduce to a minimum exposure to mechanical vibration and the attendant risks. The directive requires that workers exposed to mechanical vibration in excess of the exposure action values shall be entitled to appropriate health surveillance. However, health surveillance is not restricted to situations where the exposure action value is exceeded: health surveillance is required if there is any reason to suspect that workers may be injured by the vibration, even if the action value is not exceeded.

According to ISO 5349-1,²⁷ the onset of finger blanching would be expected in 10% of persons after 12 years at the EU exposure action value and after 5.8 years at the exposure limit value. The exposure action value and the exposure limit value in the directive do not define *safe exposures* to hand-transmitted vibration.¹⁷

Figure 8 Hand-transmitted vibration exposure limit value [$A(8) = 5.0 \text{ m s}^{-2} \text{ rms}$] and exposure action value [$A(8) = 2.5 \text{ m s}^{-2} \text{ rms}$] in the EU Physical Agents (Vibration) Directive.¹⁵

4.4 Preventative Measures

When there is reason to suspect that hand-transmitted vibration may cause injury, the vibration at tool-hand interfaces should be measured. It may then be possible to predict whether the tool or process is likely to cause injury and whether any other tool or process could give a lower vibration severity. The duration of exposure to vibration should also be quantified. Reduction of exposure time may include the provision of exposure breaks during the day and, if possible, prolonged periods away from vibration exposure. For any tool or process having a vibration magnitude sufficient to cause injury, there should be a system to quantify and control the maximum daily duration of exposure of any individual. The risks cannot be assessed accurately from vibration measurements: They contribute to an assessment of risk but may not always be the best way of predicting risk. Risk may also be anticipated from the type of work and knowledge that the same or similar work has caused problems previously.

When evaluating the risks using the frequency weightings in current standards, most commonly available gloves would *not* normally provide effective attenuation of the vibration on most tools.³² Gloves and "cushioned" handles may reduce the transmission of high frequencies of vibration, but current standards imply that these frequencies are not usually the primary cause of disorders. Gloves may help to minimize pressure on the fingers, protect the hand from other forms of mechanical injury (e.g., cuts and scratches), and protect the fingers from temperature extremes. Warm hands are less likely to suffer an attack of finger blanching, and some consider that maintaining warm hands while exposed to vibration may also lessen the damage caused by the vibration.

Workers exposed to vibration known or suspected to cause injury should be warned of the possibility of vibration injuries and educated on the ways of reducing the severity of their vibration exposures. They should be advised of the symptoms to look out for and told to seek medical attention if the symptoms appear. There should be preemployment medical screening wherever a subsequent exposure to hand-transmitted vibration may reasonably be expected to cause vibration injury. Medical supervision of each exposed person should continue throughout employment at suitable intervals, possibly annually.

CHAPTER 30

EFFECTS OF MECHANICAL SHOCK ON PEOPLE

A. J. Brammer

Ergonomic Technology Center
University of Connecticut Health Center
Farmington, Connecticut
and
Envir-O-Health Solutions
Ottawa, Ontario, Canada

1 INTRODUCTION

A mechanical shock is a nonperiodic, time-varying disturbance of a mechanical or biological system characterized by suddenness and severity with, for the human body (or body segment, e.g., hand and arm or head), the maximum forces occurring within a few tenths of a second and a total duration on the order of a second. Like vibration, the long-term average of shock motion will tend to zero, although it may include translations, or rotations, or both (e.g., vertical motion experienced by passengers during aircraft turbulence). There is no clearly definable or accepted boundary for the transition from transient *vibration* to a mechanical *shock*.

An impact occurs when the human body, or a body part, collides with an object. An impact may be distinguished from a shock by the following example. An individual seated in an automobile subjected to an upward vertical *shock* acceleration in excess of that due to gravity (e.g., traversing a speed bump) will momentarily lose contact with the seat cushion and subsequently suffer an *impact* with the seat on landing. Posture, contact area, muscle tension, and the relative internal motion and stresses of body parts may differ between these situations. Thus, when considering the injury potential or discomfort of a shock or impact, the size and shape of the object in contact with, or impacting, the body or body part (e.g., hand, or head) is important, as is the posture. The direction of application of the shock or impact to the body is equally important. Orthogonal coordinate axes are commonly specified at the seat for a seated person, with reference commonly made to *headward* [i.e., directed toward the head, i.e., in the $+z$ direction of the coordinate system defined in International Organization for Standardization (ISO) standard 2631-1¹—see Chapter 29], *tailward* (directed toward the feet, or $-z$ direction), *spineward* (directed from chest toward the spine, or $-x$ direction), or *sternumward* (directed from back toward the chest, or $+x$ direction) forces and accelerations. A separate, standardized, orthogonal coordinate system with primary (z_h) axis along on the third metacarpal is used to describe motions at the hand (ISO 5349-1²—see Chapter 29).

2 MEASUREMENTS AND METRICS

Uniaxial sensors, usually accelerometers, are employed to record instantaneous accelerations that vary with time t , as $a(t)$, with orthogonal component

accelerations commonly being combined by vector addition. Care must be taken to avoid exciting mechanical resonances within, or mechanical overloading sensors used to record large magnitude stimuli, such as those produced by some hand-held power tools (e.g., pneumatic hammers, impact drills). A common solution is to insert a mechanical filter between the accelerometer and the tool handle (see ISO 5349-2³).

2.1 Frequency Weighting

Human response to shock and impact depends on the frequency content of the stimulus, as well as the magnitude. Studies have been conducted to determine vibration magnitudes at different frequencies with an equal probability of causing a given human response. The biomechanic and biodynamic responses of the human body to external forces and accelerations can be expected to depend nonlinearly on the magnitude of the stimulus, and so any weighting of different frequencies will be applicable to a limited range of shock or impact magnitudes.

Equinoxious frequencies may be estimated, in principle, from epidemiological studies of health effects in human populations or, more commonly in practice, from the response of human subjects, animals, cadavers, or biodynamic models to the stimuli

Figure 1 Frequency weightings for whole-body and hand-transmitted shocks. W_k is for headward and tailward whole-body shocks, and W_d is for spineward, sternumward, and side-to-side whole-body shocks. W_h is for all directions of shocks entering the hand.

of interest. The frequency weightings employed for hand-transmitted shocks, and small whole-body shocks influencing ride comfort in transportation vehicles, are those used for vibration (ISO 5349-1²; ISO 2631-1¹), and are shown in Fig. 1. The range of frequencies is from 0.5 to 80 Hz for whole-body shocks and from 5.6 to 1400 Hz for shocks entering the hand. For a seated or standing person, the frequency weighting employed for the third orthogonal coordinate axis (from “side to side”) is also W_d . Frequency weightings for whole-body shocks likely to cause spinal injury are implicit in the biodynamic models used for their evaluation. The frequency weighting for the dynamic response index (DRI), which has been used extensively to evaluate headward whole-body shocks, is shown by the thick continuous line in Fig. 1. The frequency weightings are applied to acceleration–time histories, $a(t)$, by means of electronic filters or, implicitly, by the application of a biodynamic model as described in Section 4.

2.2 Characterizing the Magnitude of Shocks

The magnitude of a shock may be characterized by second, and higher, even-order mean values of the time history of the acceleration or by the output of biodynamic models. In the former case, the time history is commonly frequency weighted to equate the hazard at different frequencies, $a_w(t)$, that is, the mean value is

$$a_{RM} = \left[\frac{1}{T} \int_0^T [a_w(t)]^m dt \right]^{1/r} \quad (1)$$

where the integration is performed for a time T , and m and r are constants describing the moment and root of the function. The higher order moments provide progressively greater emphasis to the components of the motion with larger amplitudes compared to the *root-mean-square* (rms) acceleration a_{rms} , which is obtained from Eq. (1) with $m = r = 2$ and is the primary magnitude metric for human response to vibration. More appropriate metrics for shocks include the *root-mean-quad* (rmq) acceleration a_{rmq} , with $m = r = 4$,⁴ and metrics with higher even-order moments, such as with $m = r = 6$.

2.3 Characterizing Exposure to Shocks

A generalized expression for exposure during a time T to a stimulus function that has often been frequency weighted to equate the hazard at different frequencies, or transformed to estimate the internal motion of a body part, $F(a_w(t))$ may be written

$$E(a_w, T)_{m,r} = \left[\int_0^T [F(a_w(t))]^m dt \right]^{1/r} \quad (2)$$

As already noted, $F(a_w(t))$ may be expected to be a nonlinear function of $a_w(t)$, and the function may be based on the output of a biodynamic model.

Within this family of exposure functions, generally only those with *even* integer values of the moment m are of interest. The *vibration dose value* (VDV) for which $F(a_w(t)) \equiv a_w(t)$ and $m = r = 4$, may be used generally for characterizing exposure to small shocks,⁴ that is,

$$\text{VDV} = E(a_w, T)_{4,4} = \left[\int_0^T [a_w(t)]^4 dt \right]^{1/4} \quad (3)$$

Higher, even-order moment metrics (e.g., $m = r = 6$) have been proposed for exposure to repeated shocks (e.g., ISO 2631-5⁵). A related function, the severity index, for which $F(a_w(t)) \equiv a_w(t)$, moment $m = 2.5$ and root $r = 1$, is sometimes used for the assessment of head impact, although it cannot be applied to long-duration acceleration–time histories owing to the noninteger value of m . The *head injury criterion* (HIC), which was developed as an alternative to the severity index, is used to assess the deceleration of instrumented crash test dummies or anthropomorphic manikins (see Section 4.3):

$$\text{HIC} = \left| (t_2 - t_1) \left[\frac{1}{t_2 - t_1} \int_{t_1}^{t_2} a(t) dt \right]^{2.5} \right|_{\max} \quad (4)$$

where t_1 and t_2 are the times between which the HIC attains its maximum value, and $a(t)$ is measured at the location of the center of gravity of the “head.”

3 QUANTIFYING HUMAN RESPONSE TO SHOCKS

Human subjects cannot be subjected to injurious shocks for ethical reasons, and so only responses to small-amplitude shocks are obtainable from laboratory experiments. The tolerance of the human body to large single shocks has been studied in the past: Such experiments are, however, unlikely to be replicated. Some information has been obtained from studies of accidents, although in most cases the input acceleration–time histories are poorly known. An exception is the single shocks powering the ejection seats of high-speed aircraft. Establishing the characteristics of shocks or impacts that result in injury to humans thus relies primarily on studies conducted with human surrogates (animal and cadavers) and predictions from theoretical models.

3.1 Experiments with Human Subjects

Human subjects have been exposed to whole-body mechanical shocks in the vertical and, most often separately, horizontal directions when sitting on a seat attached to the moving platform of a vibration exciter. For headward shocks the VDV has been shown to characterize the discomfort produced by either single or repeated shocks.⁶ A single frequency weighting function may be used in the range of

shock magnitudes with peak accelerations up to about $15 \text{ m} \cdot \text{s}^{-2} (W_k)$. However, a nonlinear relationship may be required to extend the characterization of shocks to magnitudes in which impacts may occur if the subject is not restrained by a seat harness.⁷ For the multiple whole-body shocks encountered in most commercial transportation, and industrial, settings, where exposures commonly also involve ongoing vibration, the preferred metric is the VDV calculated with a fixed frequency weighting [Eq.(3)]. The metric does not appear to be particularly sensitive to the precise form of the frequency weighting function when used to assess discomfort.⁸

The tolerance of the body to large single shocks has been studied in experiments conducted with a human subject seated on a rocket-propelled sled that is braked at the end of a test track. The subjects wore safety belts and harnesses to restrain motion during deceleration. Experiments have also been conducted using a drop tower for single tailward shocks.

The response of the hand and arm to shocks, as opposed to nonstationary random or periodic vibration, has received comparatively little attention.⁹ While it has been suggested that acute and chronic health effects may be influenced by shocks, the results of experiments are contradictory. It has been demonstrated that the total mechanical energy absorbed by the hand and arm, as well as the forces exerted by the hands to grip and control the power tool, are increased by exposure to shocks when compared with exposure to continuous vibration.¹⁰ The responses of the hand and arm to shocks are, however, considered at present to be defined by the same metric as used for vibration, namely the energy-equivalent rms exposure [i.e., $F(a_w(t)) = a_w(t)$ and $m = r = 2$ in Eq. (2)].

3.2 Experiments with Human Surrogates

The boundary between the onset of injury and survivability of exposure to single whole-body shocks has been explored by a combination of experiments involving human subjects exposed to less hazardous shocks than those believed to define the boundary and animals (chimpanzee and hog) exposed to shocks at, or exceeding, the expected boundary. The animals were positioned on the rocket-propelled sled previously described either in a seated position, for exposure to spineward and sternunward shocks, or supine, for exposure to headward and tailward shocks. The animals were instrumented with, in some cases, accelerometers surgically embedded in the back. The efficacy of various forms of restraining devices in preventing or reducing injury was also studied (e.g., lap belts, shoulder straps, and thigh straps).

The onset and extent of injury from single impacts to the head have been studied using human cadavers and animals. A rotary hammer was used to simulate impact with a hard unyielding surface to determine the acceleration-time relationship for concussion in live dogs. In related experiments, cadavers with instrumented heads were positioned horizontally and dropped so that the head impacted a steel block. The research led to the Wayne State Concussion Tolerance

Curve for impact of the forehead on a hard, flat surface,¹¹ which has had considerable influence on motor vehicle passenger compartment design. The severity index describes the relationship between peak acceleration and impact duration from about 2.5 to 50 ms.

With changing ethics regarding animal and human experimentation, it is unlikely that the historical studies on the onset of injury from single shocks or impacts will be extended or repeated. Anthropomorphic manikins have now been developed as human surrogates for evaluating "human" response to extreme shock and impact environments (e.g., crash test dummies). More complete responses can be obtained, in principle, by computer models that simulate both the shock or impact environment and the "human."

4 SIMULATION OF HUMAN RESPONSE

4.1 Single-Degree-of-Freedom Biodynamic Model: Dynamic Response Index

The biodynamic response of the human body, or a body part, can be represented by the motion of a collection of masses, springs, and mechanical dampers for frequencies up to several hundred hertz.¹² The simplest model consists of a mass m , which represents the mass of the upper body of a seated person, supported by a spring with stiffness k , representing the spine and associated musculature, and a damper, which is excited at its base, as sketched in Fig. 2.

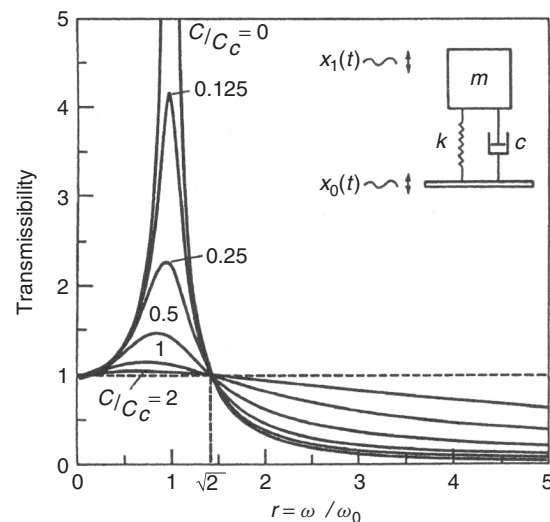

Figure 2 Single-degree-of-freedom, lumped-parameter, biodynamic model (see text). The mass m is supported by a spring with stiffness k and viscous damper with resistance c . The transmissibility of motion to the mass is shown as a function of the frequency ratio, $r (= \omega / \omega_0)$, when the base is subjected to a displacement $x_0(t)$. The response of the mass is taken to represent spinal motion. (After Griffin.⁴ Reprinted with permission.)

The transmissibility of this simple model, that is, the motion of the mass relative to that of the base (x_1/x_0), is plotted in the diagram as a function of the ratio of the angular excitation frequency, ω , to the (angular) resonance frequency, $\omega_0 = (k/m)^{1/2}$. It can be seen that for excitation frequencies less than the resonance frequency (i.e., $r = \omega/\omega_0 \ll 1$) the motion of the mass is essentially equal to that of the base. At angular frequencies greater than the resonance frequency (i.e., $r > \sqrt{2}$), however, the motion of the mass becomes progressively less than that of the base, forming a low-pass mechanical filter. At angular excitation frequencies close to the resonance frequency, the motion of the mass exceeds that of the base by an amount that depends on the damping ratio, labeled c/c_c in the diagram.

This single degree-of-freedom (DOF) biodynamic model has been used extensively to simulate the response of the spine to shocks. For headward shocks, the DRI estimates the potential for spinal injury from the maximum deflection of the spring, $|x_1(t) - x_0(t)|_{\max}$, which is calculated for a known input acceleration–time history. The metric relates the maximum compressive force of the spring, $k|x_1(t) - x_0(t)|_{\max}$, to the peak stress on the spine by assuming the cross-sectional area of the spine is proportional to the model mass, that is, by $[k/m]|x_1(t) - x_0(t)|_{\max}$. The DRI is then defined as $(\omega_0)^2|x_1(t) - x_0(t)|_{\max}/g$, where the natural frequency is 52.9 rad/s (thus making $f_0 = 8.42$ Hz), the damping ratio is 0.224, and g is the acceleration of gravity (9.81 m s^{-2}). The model has been used to predict the spinal injury rate for input acceleration–time histories corresponding to those employed in rocket-driven ejection seats for high-speed aircraft. Its success has led to its adoption for specifying ejection seat performance, and its extension to a metric for exposure to repeated shocks^{13,14} and to shocks in three dimensions.^{5,15}

4.2 Complex Biodynamic Models

Numerous, more complex biodynamic models have been developed to incorporate more realistic descriptions of individual body parts and to predict the motion of one body part relative to another.^{16,17} The mathematical dynamical model (MADYMO), which employs a combination of rigid bodies, joints, springs, and dampers to represent the human, or in some cases anthropomorphic manikin, is a comprehensive computer model for predicting the response to whole-body shocks. A MADYMO typically employs 15 ellipsoidal segments with masses and moments of inertia determined from anthropomorphic data for adults and children. The connections between these segments are flexible and possess elastic and resistive properties that are characteristic of human joints. The environment to be simulated may include the interior surfaces of vehicles or cockpits (e.g., seats and dashboard) and occupant restraints. The model may also simulate wind forces to estimate pilot motion after ejection from an aircraft.

There does not appear to be a biodynamic model specifically designed to predict the response of the

hand and arm to the shocks experienced while operating hand-held impact power tools. MADYMO models have been developed to predict the detailed response of some body parts to a simulated environment using finite elements (FEs), which can interact with the multibody model elements. Examples of human body subsystems that have been modeled with FEs include the spine, to estimate forces on the lumbar vertebral disks,¹⁸ and to predict the injury potential of vertebral compression and torsional loads,¹⁹ and the head and neck, to predict forward rotation loads during rapid horizontal deceleration.¹⁷

The nonlinear response of the spine to shocks has also been modeled using an artificial neural network.²⁰ The network is first trained with human responses to known input acceleration–time functions and is then capable of predicting spinal motion in response to arbitrary input accelerations that fall within the boundaries of magnitude and frequency set by the training data. The success of a neural network in predicting the motion recorded by an accelerometer placed over the L4 vertebral spinal process when a subject was exposed to tailward shocks and impacts is shown in Fig. 3. For comparison, the spinal motion predicted by the simple biodynamic model with parameters of the DRI is shown in Fig. 3. The output of the simple biodynamic model is obtained by linear filtering using the DRI frequency weighting of Fig. 1. It would appear from these results that a nonlinear model is required to reproduce spinal motion when the input acceleration–time history includes impacts.

4.3 Anthropomorphic Manikins

Manikins that mimic the shape, weight, and some biodynamic properties of humans are used extensively for motor vehicle crash testing and for evaluating aircraft escape systems and seating.²¹ The Hybrid III manikin has become the de facto standard for simulating the response of motor vehicle occupants to frontal collisions and for tests of occupant safety systems (i.e., seat belts and air bags). The manikin approximates the size, shape, mass, and weight of the 50th-percentile North American adult male and consists of metal parts to provide structural strength and define the overall geometry (see Fig. 4).

The “skeleton” is covered with foam and an external vinyl skin to replicate the shape of the 50th-percentile male. The manikin possesses a rubber lumbar spine, curved to mimic a sitting posture. The head, neck, chest, and leg responses are intended to replicate human head acceleration resulting from forehead and side-of-the-head impacts; fore-and-aft, and lateral, bending of the neck; deflection of the chest to distributed forces on the sternum, and impacts to the knee, during rapid deceleration.²² Instrumentation to record these responses as well as other parameters are indicated in Fig. 4. Hybrid III dummies are available for small (5th percentile) adult females and large (95th percentile) adult males, as well as for infants and children. A related side impact dummy has been developed.

Figure 3 Comparison between the measured (continuous line) and predicted (dashed lines) response of the spine (above L4) to shocks and impacts: (a) nonlinear neural network model and (b) DRI model. (From Nicol et al.²⁰ Reprinted with permission.)

Figure 4 Sketch of Hybrid III anthropomorphic dummy designed for use in motor vehicle frontal crash tests, showing elements of construction and sensors. (From AGARD-AR-330.²¹ Reprinted with permission.)

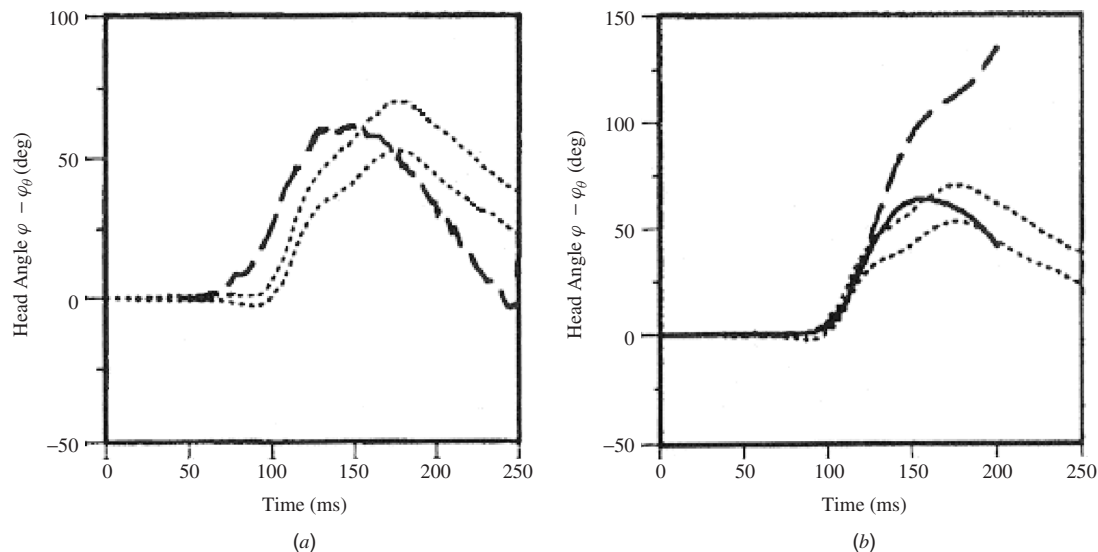

Figure 5 Comparison between the response of human volunteers (dotted lines), a manikin, and a mathematical biodynamic model of the head and neck to $150 \text{ m} \cdot \text{s}^{-2}$ spineward deceleration. (a) Response of Hybrid III head and neck (dashed line) and (b) response of three-dimensional MADYMO model of the head and neck with passive neck muscles (dashed line) and active neck muscles (continuous line). (From RTO-MP-20.¹⁷ Reprinted with permission.)

Manikins have also been developed by the Air Force for use with aircraft ejection systems. The Advanced Dynamic Anthropomorphic Manikin (ADAM) is conceptually similar to that of the Hybrid III dummy and, in addition, attempts to replicate human joint motion, soft tissue, and the response of the spine to vertical accelerations for both small-amplitude vibration and large impacts. The spine consists of a mechanical spring-damper system (see Section 4.1) that is mounted within the torso.

The potential limitations of mechanical models for predicting nonlinear human responses to shock and impact may be overcome, in principle, by introducing active control systems. At present, only simple active biodynamic models have been demonstrated for use in seat testing.²³

4.4 Biofidelity of Biodynamic Models and Human Surrogates

Knowledge of the biofidelity of a biodynamic model or human surrogate is essential in order to relate the results to those expected with human subjects. This inevitably requires human subjects to be exposed to the same stimulus as the model or surrogate and hence limits comparisons to noninjurious shocks and impacts. Nevertheless, it is instructive to compare the time histories of some responses. A comparison between the responses of human volunteers, the range of which is shown by dotted lines, with those of the Hybrid III manikin and of a three-dimensional head and neck MADYMO model to a sternward deceleration are shown in Figs. 5a and 5b, respectively.

Inspection of Fig. 5a reveals that forward rotation of the head of the Hybrid III does not fall within the values defined by the human subjects, although the manikin does reproduce the maximum angular rotation of the head but at the wrong time after the onset of the shock. The MADYMO model also predicts head rotation that falls outside the range of values defined by human subjects when muscle behavior is not included. The inaccuracy can be overcome in this case by including muscle tension in the computer model (continuous line in Fig. 5b). It may be inferred from these results that the intrinsic mechanical damping of the neck of Hybrid III does not closely replicate the human response, and active “muscle” forces are necessary.

Employing the results of experiments with live animals to predict biodynamic responses in humans introduces uncertainties associated with interspecies differences. Of particular concern are the differences in size and mass of body parts and organs, which influence resonance frequencies. For this reason, most animal research has employed mammals of roughly similar size and mass to humans (i.e., hogs and chimpanzees).

As with manikins, human cadavers lack appropriate mechanical properties for tissues and muscle tension. The latter is important for obtaining realistic human responses, as has already been noted.

5 HEALTH, COMFORT, AND INJURY CRITERIA

There is an extensive literature on the effects of shock and impact on humans.^{4,24} For small-amplitude whole-body shocks, the primary response is of reduced comfort in transportation vehicles. The ability to perform

common tasks (e.g., writing, reading, drinking from a cup) is also impeded. Large-amplitude headward and tailward whole-body shocks can injure the spine when seated, and headward shocks can also injure the feet and ankles when standing. The response and injury potential will depend on the peak magnitude of the shock acceleration and its time history. The response to shocks in all directions will be influenced by the effectiveness of body restraints in restricting the relative displacement of body parts (e.g., “flailing” of arms and legs and “torpedoing” of torso through harness) and in preventing impacts with surrounding structures. The combination of extreme shock and impact can cause bone fracture and soft tissue (e.g., organ) injury. Fatal injury may result from exposure to large shocks or impacts. The consequences of impacts to body parts are influenced by the velocity, duration, area of impact, and transfer of momentum (e.g., bullet versus basketball) and, for the head, may involve fatal or nonfatal concussion, contusions, skull fracture, and axonal brain injury. Hand-transmitted shocks have not been conclusively demonstrated to lead to more rapid onset or extreme symptoms of the hand–arm vibration syndrome, even though this is suspected, and so are currently assessed by the criteria used for hand-transmitted vibration that are described in Chapter 29. The criteria described here are for discomfort and injury and survivability from exposure to whole-body shocks. There are, however, no universally accepted procedures or metrics.²⁵ Unfortunately, even consensus standards prepared for the same application (e.g., discomfort) contain significant incompatibilities.²⁶

5.1 Discomfort – No Impacts

Exposure to shocks of insufficient magnitude to cause severe health effects may influence ride comfort in vehicles, aircraft, and boats. The VDV is correlated with subjective assessments of discomfort from

exposure to shocks, with the expected rating for motions judged to produce “severe discomfort” listed in Table 1. The acceleration–time histories are frequency weighted by W_k or W_d depending on the direction of the shocks relative to the body (see Fig. 1). The VDV is an acceptable metric for motions involving whole-body vibration as well as shocks and is suggested here for “small” shocks with peak accelerations up to about $15 \text{ m} \cdot \text{s}^{-2}$, provided the person is restrained.²⁷ The risk of injury should be considered for exposures involving shocks of greater magnitude (see Section 5.2).

The VDV provides a linear measure of the motion and may therefore not serve as an appropriate metric for nonlinear motions, such as those involving impacts (see Fig. 3). It should also be noted that motions considered unpleasant in most circumstances may in others be considered acceptable and even exhilarating (e.g., fairground rides).

5.2 Risk of Injury from Multiple Shocks and Impacts

A general method for assessing the risk of injury to a healthy seated person from exposure to multiple shocks and impacts has recently been proposed.³¹ The method consists of three parts: a dynamic response model to predict the transmission of the motion from the seat to the spine; identification of acceleration peaks and their accumulation to form the dose at the spine; and an injury risk model for assessing the probability of adverse health effects based on the cumulative fatigue failure of repeatedly stressed biological materials.³² The dynamic response model employs the nonlinear biodynamic model described in Section 4.2 for headward and tailward shocks and impacts, and (linear) single-degree-of-freedom biodynamic models for the other directions (see Section 4.1). The inputs to the

Table 1 Health, Comfort, and Injury Criteria for Healthy Adults

Human Response	Metric	Weighting, Model, or Manikin	Value	Source
Discomfort (severe) – no impacts				
Small shocks, any direction	VDV	W_k , or W_d	$15 \text{ m/s}^{1.75}$	BSI 6841 ²⁷
Risk of injury from shocks and impacts (up to $40 \text{ m} \cdot \text{s}^{-2}$)				
Many shocks, any direction	$E(\Sigma a_{\text{peak}})_{6,6} \Rightarrow$ compress spine	Nonlinear (4.2) and single DOF (4.1) models	$>0.5 \text{ MPa}$	ISO 2631-5 ⁵
Risk of injury from shocks – subject restrained, no impacts				
Large shocks, headward, tailward ^a	$E(\text{DRI}_q, n_q)$	DRI model	9.0	ASCC 61/25 ²⁸
Survivable single shock, or impact				
To body, headward shock ^a	DRI	DRI model	18	After von Gierke ¹²
To body, spineward shock ^a	Peak acceleration		See Fig. 6	Eiband ²⁹
Head impact (manikin)	HIC	Hybrid III	1000	NHTSA ³⁰
To neck, flexion (manikin)	Moment	Hybrid III	190 N.m	NHTSA ³⁰
To neck, extension (manikin)	Moment	Hybrid III	57 N.m	NHTSA ³⁰

^aWhen body restrained.

dynamic response models are the seat motions measured in the three orthogonal directions (x , y , and z). The acceleration dose is constructed separately from the peak acceleration of each shock at the spine that causes compression, or lateral motion, $a_{\text{peak}}(t)$, as calculated from the output of the appropriate biodynamic model using Eq. (2) with $F(a_w(t)) \equiv a_{\text{peak}}(t)$ and $m = r = 6$. The combined acceleration dose applicable to an average working day is converted into an equivalent *static* compressive stress, which may then be assessed by a Palmgren–Miner model for fatigue failure of the vertebral end plates.³¹ The calculation takes into account the reducing strength of the vertebrae with age. A lifetime exposure to a static stress of less than 0.5 MPa is associated with a low probability of an adverse health effect, whereas lifetime exposure to a static stress in excess of 0.8 MPa has a high probability of spinal injury.⁵ The nonlinear biodynamic model is based on human responses to peak accelerations of up to 40 m s^{-2} , and so the method should not be applied to shocks and impacts of larger magnitude. This restriction has limited practical consequences, as such motions are unlikely to be tolerated in commercial transportation systems.

5.3 Risk of Injury from Large Shocks When Subject Restrained

For “large” single or multiple shocks in the headward or tailward direction, that is, with peak accelerations greater than about 40 m s^{-2} , the method proposed by Allen¹³ and adopted by the Air Standardization Coordinating Committee,²⁸ which is conceptually

similar to that just described, is recommended for single or multiple shocks (no impacts). It is based on the DRI (see Section 4.1), which is extended to include multiple shocks and used to estimate the risk of spinal injury in healthy young men, using the theory of cumulative material fatigue damage. The model is applicable to persons who are seated and restrained by seat harnesses. The metric depends on the number of shocks experienced and is presented in the form described by Payne.¹⁴ For exposures consisting of multiple shocks of differing magnitude, if there are n_q shocks of magnitude DRI_q , where $q = 1, 2, 3, \dots, Q$, then the dose can be expressed as

$$E(\text{DRI}_q, n_q) = \left[\sum_{q=1}^Q n_q (\text{DRI}_q)^8 \right]^{1/8} \quad (5)$$

The metric is applied here to the shocks experienced during a “day,” normally expected to be no more than 8 h so that there is time for recovery between exposures. As the maximum value listed in Table 1 is applicable to healthy young men, it is to be expected that a more conservative value should be used when applying the procedure to older persons.

5.4 Survivable Single Shocks or Impacts

Estimates for *survivable* exposures of humans to single shocks are given for headward acceleration in Table 1 and for spineward deceleration in Fig. 6.

For headward acceleration, the accumulated operational experience with nonfatal aircraft ejections from

Figure 6 Human tolerance of single, spineward shocks expressed as a function of the magnitude and duration of seat deceleration. (After Eiband.²⁹ Reprinted with permission.)

military aircraft suggests that a DRI of 18 is associated with a tolerable rate of spinal injury (<10%) among healthy, young male pilots who are restrained in their seats by conventional flying harnesses.¹² For spineward acceleration, the most reliable estimate is from the rapid deceleration of human volunteers and animals seated on a test sled with body restraints and is summarized in Fig. 6.²⁹ The limit of human tolerance is indicated by the boundary of severe injury, which depends on the duration of the peak acceleration and the rate of onset of the deceleration. The curve is a composite of injurious exposures to animals and extrapolations from exposures involving human subjects.

An alternative approach is to specify tolerance limits for measurements conducted on anthropomorphic manikins subjected to single shocks or impacts. The HIC has been applied to the motion of the center of gravity of the head of the Hybrid III manikin in motor vehicle crash tests prescribed by the U.S. National Highway Traffic Safety Administration (NHTSA), using a time interval ($t_2 - t_1$) of 36 ms [see Eq.(4)]. The value in Table 1 is the maximum allowable by the NHTSA for frontal collisions and is considered to represent a "concussion tolerance level."³³ Values are also listed in the Table for the most common neck injury ("whiplash").³⁴ Survivable fracture limits for the pelvis, patella, and femur in frontal and side impacts have also been proposed for manikins.²² Caution must be exercised in applying these data to humans, however. In particular, the rank ordering of the severity of head injuries in humans by the HIC values recorded on the Hybrid III has been questioned^{35,36} and may reflect its biofidelity (see Section 4.4).

1 INTRODUCTION

In many industrial and military situations, it is not practical or economical to reduce the noise to levels that do not present either a hazard to hearing or annoyance. In these situations, personal hearing protection devices are capable of reducing the noise by up to about 45 dB, depending on their design and the sound frequency. A properly selected and fitted personal hearing protection device or a combination of them (e.g., earmuffs worn over earplugs) usually can establish sufficient reduction of noise at the ear, if not to a pleasant level at least to a harmless one. Certain types of hearing protectors can also reduce noise-induced annoyance and improve speech communication, signal detection, and audibility of desirable sounds, such as machine cues, in certain situations as described in the following. A personal hearing protection device (HPD) should be used for the whole time that one is in a noise area. If one removes the protector even for a small percentage of time, such as 5 to 10 min in a whole workday, the protection is sharply reduced.

2 HEARING PROTECTOR TYPES

Hearing protection devices can be divided into four categories according to their position relative to the ear: earplugs, semiinserts, earmuffs, and helmets.

Earplugs are inserted into the ear canal and remain there without any additional means of support. *Semiinserts*, also called supraaural HPDs, close the entrance to the ear canal without being deeply inserted into it and are supported by a head or chin band. These may be used as hearing protector and are also commonly designed as lightweight earphone systems for sound production. *Earmuffs* cover the entire outer ear with a cuplike shell, the edge of which is covered with a compliant cushion that presses and seals against the flesh. Muffs may be held in place by a headband, suspended from a hard hat via clamping arms or mounted inside a helmet. *Helmets* cover most of the head surface. They are not commonly used for ear protection alone; usually they combine this function with protection of the head against cold, impact hazards, and/or weapons threats such as gunshots.

Helmets may act also as a support for earphones or earmuffs, and if their design covers most of the head, may offer added hearing protection against the bone conduction pathway for noise that flanks the other types of HPDs.

Figure 1 shows examples of the four basic kinds of ear protectors. Each has advantages and disadvantages compared with the others.

Many other more sophisticated HPDs and special features for communications and other enhancements have arisen over the past decade, and these are typically embodied as augmentations of the basic HPD types mentioned in this section. These so-called augmented HPDs, due to their radical design departures from conventional protectors, are covered in a separate section (Section 12) herein.

3 BASIC REQUIREMENTS FOR HEARING PROTECTORS

Every HPD, irrespective of type, must comply with the requirements of (1) sound attenuation, (2) comfort, and (3) absence of adverse effects on human tissue. In addition there are three other requirements whose importance depends on the conditions of use: (4) conservation of speech intelligibility and hearing of signals, (5) ease of handling, and (6) durability.

1. The first requirement, sound attenuation, is obvious. It determines the amount of protection from noise that is afforded to the ear. The degree of sound attenuation necessary depends on the sound pressure, the kind of noise, and the duration of exposure. The exact nature of these interrelationships is somewhat obscure, but it can be stated quite generally that the amount of sound attenuation provided by an HPD should be sufficient to keep the noise level below the established safety limit (either government legislation, consensus standards, or prescribed safety practices in industry or elsewhere). All HPD will not be capable of attaining this limit. Even the best ear protectors do not attenuate more than 45 dB on the average, while an attenuation of 40 to 50 dB may be advisable under some circumstances. Limiting factors may be leakage around the HPD, sound transmission through the HPD, vibration of the HPD, and/or bone conduction of the

Figure 1 Four basic types of HPDs. (From Berger.¹)

sound around the HPD.² All of these are referred to as “flanking paths.”

2. Although comfort may appear to be a secondary requirement at first glance, it must be realized that an uncomfortable HPD becomes intolerable after prolonged wear and is typically removed, negating any protective benefit it may have. The annoyance produced by noise of very high sound pressure, to some extent, may distract the discomfort caused by ear protectors. Consequently, the requirement of comfort is most acute in a noise of moderate sound pressure, where HPDs are used for psychological rather than for physiological reasons, for example, to eliminate the distraction caused by irregular noise, to reduce noise annoyance, or to facilitate sleep.

3. A third factor, which in itself justifies discarding otherwise satisfactory ear protectors, is a toxic or allergic effect on the skin. An HPD may lead to inflammations that cannot be controlled except by discontinuing its use. Fortunately, by careful selection of materials that contact the skin, nontoxicity is the easiest requirement to fulfill.

4. Whenever the noise level is low enough to permit speech communication and/or hearing of signals, the acoustical performance of the HPD should be such as to assure the highest possible speech intelligibility and audibility. Special devices designed to meet this requirement are discussed in Section 12 herein.

5. Ear protectors are effective only when used correctly. This is more easily achieved when their application is simple, and when they are properly selected for the individual user based on anthropometric size and fit. Sizing and fit issues are commonly encountered with “one size fits all” or multisized earplugs, but also the proper fit of earmuffs depends heavily on their design, such as headband height, width, and compression force on the cushions. If HPDs are difficult to handle and apply, the probability of incorrect use increases, and with it the variability of their protective performance.

6. The durability of an HPD is an economic factor and becomes important when large quantities are purchased. In general, more durable devices are more economical in the long run.

4 COMFORT AND OTHER REQUIREMENTS

Pressure Pressure exerted by an HPD on the skin and underlying tissue and bone is probably the most direct cause of discomfort. If the pressure is strong and continues for a relatively long period of time, the pain may become intolerable. Two factors are involved, the total force of the ear protector against the skin and the distribution of the pressure.

The total force exerted by an earplug results from the ratio of its cross-sectional dimensions, the corresponding dimensions of the ear canal, and material density. For instance, a small-diameter earplug is generally more comfortable than a large-diameter one, unless, of course, the smaller earplug is inserted too deeply into the bony part of the ear canal or if it feels unstable as if it will fall out of the ear. The pressure exerted by earmuffs and semi-inserts varies proportionally with the force applied by their supporting means. A helmet creates a more complicated situation, and the total force depends partly on size, weight, and the distribution of head contact points of the helmet's liner cushion.

When the total force is distributed over a large area, the resulting pressure is smaller than when it is concentrated on a few spots. For this reason an earplug shaped to fit the contours of the auditory canal and made of a soft, conformable material that permits individual adaptation is more comfortable than a poorly shaped or noncompliant plug. The same is true for the sealing cushion of an earmuff or a semiinsert. In order to ensure a large area of contact with the skin, earmuffs and semiinserts should not only be of a size and shape compatible with the anatomy, but they should also be made of a compliant material.

When the area of contact between the ear protector and the skin is large, the total force acting on the flesh lining must be limited to a value that permits proper circulation of the blood. A certain amount of pressure on the skin is necessary to hold the ear protector in place and to provide sound attenuation. As the pressure diminishes, the impedance of the skin decreases and the vibration of the ear protector as a rigid body increases. With too little pressure air leaks may be created.

It is difficult to specify the maximum pressure acceptable for earplugs. Experience shows that, on the average, three to five sizes are sufficient to fit most ears, and a few earplugs (e.g., the venerable V-51R), are available in up to five sizes. The largest size that can be tolerated affords the maximum sound attenuation. Most earplugs, however, are designed to be one size fit most, and this quality can be reasonably established with multiflanged polymer earplugs or user-molded foam, wax, or spun fiber devices.

There are several investigators that have studied the effects of pressure and cushion force on comfort, including limits on those parameters (e.g., see the review in Casali and Grenell,³ but little empirically derived design information currently exists. Pressure on the very sensitive pinna should be avoided as far as possible. Pressure limits have not been specified for semiinserts, but pressure just sufficient to hold

the semiinsert in place (and *not* as the basis for establishing a pneumatic seal) seems to be adequate.

Weight The weight of an HPD affects comfort directly because the force of gravity presses the device against the skin and indirectly because the force required to hold the device in place increases as the weight increases. The following weights are suggested: an earplug should weigh on the order of 1 to 5 g, an earmuff or an earphone mounted in a socket below 350 g, and a semiinsert assembly around 18 g. Too little weight is not advisable since sound attenuation, at least for most materials, becomes lower as the weight decreases.

Temperature Ambient temperature can affect both the acoustical performance and the comfort of an HPD. Some materials, such as waxes, become very soft at high temperatures, and air leaks and increased sound conduction through the material may result. In other devices, a moderate softening of the material at body temperature may improve the conformability, thus improving the seal and comfort.

Temperature may raise more serious problems with large hearing protectors, such as earmuffs and helmets, than with small ones. By providing heat insulation, they tend to raise the temperature of the head. In a cold climate this may be welcome but in a hot climate it becomes annoying. In addition to the discomfort caused by heat, evaporation of perspiration is almost impossible and buildup of humidity under the HPD occurs. Muff cushions made in part of absorbent materials improve this situation. They have other disadvantages, however.

They typically cannot be disassembled and washed, and if they are not changed frequently they may become unhygienic. Consequently, earmuffs should cover the smallest possible area of the head surface while still accommodating the pinnae; the area of contact with the skin of helmets should also be kept to a minimum; and if possible, ventilation can be provided, especially in the case of muffs with helmet.

Wearing Time and Comfort The longer discomfort exists, the more annoying it becomes and the more likely the HPD will be removed. For a short period of time, even hard, poorly shaped earplugs can be tolerated. On the other hand, HPDs that seem quite comfortable during the first minute may become intolerable after a half hour or so. Some particularly high-attenuation earplugs can be tolerably worn during short periods of exposure to intense noise, but only a few are sufficiently comfortable to wear for an 8-h period or during a whole day or night. In addition to the direct discomfort caused by pressure, long wearing periods accentuates the adverse effects of temperature and toxicity.

Toxicity Some materials affect the skin chemically and cause inflammation or other allergic reactions. As a matter of fact, any material can probably cause skin irritation under a given set of circumstances. Toxic effects cannot be eliminated completely because

some are the result of an allergy. Materials are available, however, that cause allergy only in rare cases and are otherwise practically free from toxic effects on the skin, even over long periods of use. Polymerized chloroprenes (neoprene) and polyvinyl chloride copolymers (vinylite) are generally nontoxic when compounded with nontoxic plasticizers. Since the testing of new materials takes a great deal of time, it seems advisable, at least for the present, to use these and other materials known from experience to be chemically neutral to the skin.

Washability If an ear protector is designed for repeated use, it should be washable. It should be resistant to damage not only due to water and soap but also to antiseptics, such as alcohol. Smooth surfaces of impermeable material lend themselves better to cleaning than do absorbent materials such as chamois or porous materials such as sponge rubber.

The requirement of washability should not be applied indiscriminately, however. Some earplugs are intended to be thrown away after one use and do not require washing. For some purposes, such as in the food processing industry, disposable earplugs are more readily accepted than "permanent" washable ones. Earmuffs are too expensive to be used only once, but they can be isolated from the skin by a disposable tissue or other inexpensive material, though such materials may impact attenuation.

Durability Durability, like washability, is not a universal requirement; for example, it is superfluous for very inexpensive earplugs designed to be used only once. "Permanent" devices, however, which may be less costly in the long run, should last as long as possible. Consequently, they should be reasonably rugged and made of a material resistant to aging. Many factors can speed up the aging process, but the most important seem to be ear wax, perspiration, humidity, light, ozone, and even some active chemicals contained in the air. Materials of the neoprene or vinylite type, when compounded with appropriate ingredients, are resistant to most of these influences and may last for 2 or more years without objectionable changes. Most of the soft resilient materials, however, show a tendency either to contract and harden with time or to expand and become too soft; in either case, the distortion of shape and material breakdown degrades attenuation.

Ease of Handling Ease of handling is often slighted; yet it contributes a lot to the performance of an HPD. A complicated device or one that has to be applied with precision may give excellent results in the laboratory but thereafter fail in the field because of incorrect use. The way in which an HPD is to be applied should be as obvious as practicable; its performance should not depend heavily on instructions that dictate precise placement. Three properties facilitate easy placement: mechanical simplicity, symmetry, and adaptability.

5 SELECTING HEARING PROTECTION

A correctly selected hearing protector should provide enough noise reduction to remove the risk of hearing

Figure 2 Effect of percentage of time typical hearing protection is worn on the effective noise reduction experienced by the wearer, conserving 5-dB exchange rate. (From Berger.¹)

damage (as discussed below), and at the same time allow communication with others and hearing of signals while ensuring reasonable comfort. The selection and the acceptance of an HPD is strongly linked to the comfort it affords. The users should participate in the selection of HPDs. This selection should be based on several pointed aspects, but it should also include the final user opinion.

It should be emphasized that the HPD should be used for the whole time that one is in a noise area. If one removes the protector even for a small percentage of time, such as 5 to 10 min in a whole workday, the protection is sharply reduced, as shown in Fig. 2.

6 EVALUATION OF HEARING PROTECTORS

In most countries, the required tests concern primarily noise attenuation, although in some areas, mechanical tests, comfort, and toxicity are also addressed by the testing standards. In all cases known to the authors, evaluation tests comprise in-laboratory tests. In some cases, field tests are used for validation purposes.

6.1 Attenuation Tests

Of the various tests on ear protectors, those of sound attenuation at the ear are the most widely known. These tests are still not entirely satisfactory because: (1) the reproducibility of the data from one laboratory to another with sufficient agreement is often lacking, and (2) the results from most test protocols, with the exception of all but the most recent standards (e.g., ANSI S12.6-1997—Method B⁴), are not representative of actual attenuation achieved in the industrial or military workplace.

Most present-day tests use human subjects and psychophysical (listening-based) methods, but efforts continue to develop microphone-based "objective" tests

Figure 3 Sound flanking pathways for hearing protectors. (From Berger.¹)

that can replace the psychophysical-based “subjective” methods. These efforts have largely failed for the following reasons. These include the fact that the sound attenuation provided by an HPD is dependent at least in part on the anatomical and mechanical properties of the human head and ear and how these structures behave when an HPD is applied. Furthermore, the objective tests do not accommodate the real influences of human variability in head/ear size and anthropometry, which greatly affect the performance of the HPD as worn.

6.2 Hearing Protector Attenuation

The maximum protection offered by an HPD is dependent on the frequency of the noise; in the most basic sense, the attenuation is much more limited at the low frequencies than the high. Despite the presence of an HPD, noise can still reach the inner ear of the person wearing the hearing protector by one or more of the following pathways (see Fig. 4):

1. Leakage around the protector’s contact with the head (for muffs) or ear canal (for earplug)
2. Vibration of the protector causing sound generation in the outer ear canal
3. Sound transmission through protector materials
4. Bone and tissue conduction through of the head

The four leakage pathways set practical limits to the noise attenuation provided by any ear protector (Fig. 3). The maximum possible attenuation of the protector is unlikely to be achieved for various reasons, for example, protector–wearer coupling seal, but approximate values for wearers of both plugs and muffs are between 40 to 60 dB depending on the frequency bands.⁵

The noise attenuation of a hearing protector is best represented by the *insertion loss* (IL), which is the difference between the sound pressure levels at the outer ear canal with and without the hearing protector.

Working environments are generally semireverberant fields characterized by broad or narrow-band frequencies. Therefore, any test method for measurement of hearing protector attenuation must reasonably represent this situation.

6.3 Hearing Protector Attenuation Measurements

Several national and international standards are available for the laboratory determination of hearing protector noise attenuation, mainly the American National Standards Institute (ANSI) standard used in the United States and International Organization for Standardization (ISO) and other recommendations and standards such as EN, OSHA, and NIUSH (see references at end of this chapter) used in Europe.

The method specified by the U.S. Environmental Protection Agency (EPA) for determining (and labeling) the amount of noise attenuation that an HPD provides is based on subjective tests of protectors as worn by listeners rather than objective tests from an electromechanical device. The actual test method is called the real-ear attenuation at threshold (REAT) test, and the techniques for measuring REAT, as presently required by the EPA, are specified in ANSI S3.19–1974,⁶ which requires auditory thresholds be obtained from a panel of 10 normal-hearing listeners sitting in diffuse random-incidence sound field. The test signals are pulsed on one-third-octave bands of noise, which have center frequencies of 125, 250, 500, 1000, 2000, 3150, 4000, 6300, and 8000 Hz. Thresholds are determined with listener’s ears open and with their ears occluded by the hearing protector under test, and this is an important point—with the protector fit by an experimenter to obtain an optimal seal. The decibel difference between the open-ear threshold and the occluded-ear threshold at each frequency is the REAT in decibels for that frequency. Each listener is tested

three times with his or her ears open and three times with the ears occluded. Open and occluded tests should be counterbalanced. The REAT values for all 10 listeners are arithmetically summed, and the mean attenuation is calculated for each test frequency. Since there are three REAT values at each frequency for 10 listeners, the average calculated by dividing the grand total by 30 to obtain the grand mean. The standard deviation is also calculated for each test frequency using the number 29 (using $n - 1$ from the formula for the standard deviation of a sample, where n is the number of samples) as the denominator, as if 30 separate subjects had provided one REAT each per test frequency.

When a REAT is being determined for the purpose of labeling hearing protectors according to EPA labeling requirements, the protector is fitted into the ear or placed on the head by the experimenter in order to obtain maximum protector performance. Technically, the experimenter-fit described in ANSI S3.19-1974⁶ and adopted by the EPA does permit the test subjects to fit the protector themselves (using a fitting noise to adjust the device for maximum attenuation) provided that the experimenter personally checks each installation for good fit and acoustical seal and reinserts or readjusts the protector as necessary. In practice, however, experimenter-fit is generally taken to mean that the experimenter always personally fits the device under the test.

The European community also relies upon REAT for determining hearing protector attenuation (EN 24869⁷ and EN 352⁸). However, there are differences in methods between the ISO and ANSI standards. The number of subjects required in ISO 4869-1⁹ is 16 rather than 10, and each subject is tested only once with ears open and once with ears occluded to produce one REAT at each test frequency. In addition, ISO 4869-1 relies upon a subject-fit in which the listeners fit the hearing protectors using a fitting noise to adjust the protectors for best perceived attenuation but without feedback from the experimenter. Because of the lack of intervention by the experimenter in fitting the protector on the test subject, when hearing protectors are tested for European markets, the reported REATs are usually lower than when they are tested for distribution in the United States under ANSI S3.19-1974, Experimenter-Fit.⁶

In 1997, a new ANSI standard was approved (ANSI S12.6-1997⁴ [Method A and B]). Method B, subject-fit protocol utilizes audiometrically qualified subjects who are trained and experienced in psychophysical threshold testing but *naïve with respect to use of hearing protectors*. These subjects fit the protectors on themselves after reading *only* the manufacturer's instruction, and they receive no assistance whatsoever from the experimenter. Method B has been demonstrated to provide data that approximate the protection that can be attained by a group of informed users in the workplace within a well-managed and well-supervised hearing conservation program.¹⁰ The octave band results measured using the new standard can be converted to a single number called noise reduction ratio for subject fit (NRRsf).¹¹ This number is the single-number rating (SNR) for 84% of the population (see ISO 4869-2⁹)

less 5 dB. The NRRsf may be subtracted from the A-weighted sound pressure level (or L_{eq}) exposure to give directly the protected level for 84% of the users.¹²

6.4 Single-Number Ratings of Attenuation

The mean attenuation and standard deviations as reported by HPD suppliers have been used to calculate all ratings of protectors' performance according to the various methods in a compendium published by the National Institute for Occupational Safety and Health (NIOSH).¹³

The NRR is a single-number rating method that attempts to describe an HPD based on how much the overall (broadband) noise level is reduced by the device. The NRR is described in 40 CFR part 211 EPA Product Noise Labeling Law, subpart B hearing protective devices¹⁴ and was adopted by the EPA from Method 2 in the first NIOSH compendium.¹⁵

The NRR is intended to be used for calculating the exposure under the HPD by subtracting it from the C-weighted environmental noise exposure level. Thus, if a protector has an NRR of 17 dB and it is used in an environmental noise level of 95 dB time-weighted average for an 8-h day, the noise level entering the ear could be expected to be 78 dB or lower in 98% of the cases. An alternative use of the NRR is with A-weighted noise level exposure measurements, wherein the NRR can be applied if 7 dB is first subtracted from its value. Thus, for the same protector above, if it is used at an environmental A-weighted noise level of 90 dB, then the A-weighted noise level entering the ear is $90 - (17 - 7) = 80$ dB.

In Europe, rating systems (ISO/DIS 4869-1992⁹) have been adopted using a single number rating (SNR), the high-middle-low (HML) rating, and the assumed protection value (APV). These methods are based on REAT values measured according to ISO 4869-pt.1-1992⁹ for one-third-octave bands in octave steps from 63 to 8000 Hz (when data for 63 Hz are not present, the summation occurs from 125 to 8000 Hz). All of these methods provide the user with the option of selecting a protection performance value, which is an indication of the percentage of test subjects who achieved the specified level of noise reduction.

6.5 Headband Force of Earmuffs

As discussed above, with earmuffs, comfort will suffer if the head band force is too large. However, sufficient force is necessary for a quality fit of the hearing protector, which is in turn needed for establishing sufficient sound attenuation. Therefore, it is necessary to measure the headband force and also to use the measured force for quality control and other muff evaluations, such as useful work life. ANSI S3.19-1974⁶ shows a mechanical device for headband force measurements. The EN 352-1,⁸ 1993, standard shows a more accurate, mechanical/electric device. There is between 2 and 5% variation in the measured force. The applied pressure is actually more important than the headband force for acceptability comfort.³ Hearing protectors with broad cushions will give less pressure with the same force.

6.6 Simultaneous Use of Two HPDs (Double Hearing Protection)

Many noise situations exist where the use of a single protector is not sufficient, particularly in the military and in a few industries. In these cases the use of "combined" protection (earmuff worn over earplugs) should be considered. However, because such noise exposures are usually very severe, extreme care is required and the performance of the combination should be known before use. Tests have shown that the performance of combination protection is not the arithmetic sum of the protectors' attenuation but instead, is something on the order of 5 to 15 dB more than the performance of the better of the two HPDs involved (EN 458).¹⁶

Berger et al. (page 321)¹⁷ showed that at and above 2 kHz most earplug-plus-muff combinations provided attenuation that is approximately limited by the bone conduction flanking path (see Fig. 10.20 in Berger et al.¹⁸). Any extra attenuation gained varied between 0 and 15 dB for the better of the individual devices. The increase in NRR is between 3 and 10 dB when compared with the higher of the two individual protectors.

7 CONSIDERATIONS IN THE SELECTION AND USE OF HEARING PROTECTORS

Although the demonstrated noise reduction capability is arguably the most important factor to consider in the selection of hearing protection devices, several other points are also very important. Studies by Casali¹⁹ and Riko and Alberti²⁰ on the effectiveness of hearing protectors suggest that workers are most likely to demonstrate consistent wearing of devices that are comfortable and easy to insert, regardless of the amount of attenuation they provide. Additional thought must be given to the worker's physical limitations, including concurrent use of safety glasses or eyeglasses, the need for the worker to hear warning signals, and the need to communicate verbally. The environmental conditions of the workplace, such as temperature, confined working spaces, or the wearing of additional personal protective devices (hardhats, safety glasses, respirators, etc.), also warrant consideration. The durability (shelf life or useful life) and hygienic issues posed by each type of HPD, as well as the length of time it will be worn, are also factors that should not be overlooked. Custom-molded earplugs are a viable HPD option for many individuals, but it is important to ensure both the expertise of those who will obtain the impression as well as those who will manufacture the final earplug.

To ensure that a worker receives the most effective attenuation from the use of an HPD, the worker should be trained in the use, care, and maintenance of the device. All HPDs, including user-molded earplugs and adjustable earmuffs, require good instruction. This training should be updated on a regular basis and should be provided by appropriately trained personnel.

Comfort is a personal matter. Many users would say that HPDs, as a class of personal protection equipment

(PPE), are generally uncomfortable. But with careful selection, fitting, and consideration of the environment of use, acceptable HPDs can in fact be matched to users. It is generally reasonable advice that a choice of HPDs that are adequate for the exposures faced should be provided to each worker. In fact, this is required by the OSHA hearing conservation amendment.²¹

Hearing protectors cannot be depended upon for complete protection unless they are selected properly and worn adequately and properly throughout the time of exposure. But, comfort can work against protection achieved; for example, small earplugs or weak headband springs on earmuffs may be more comfortable but offer low noise attenuation.

8 REAL-WORLD ATTENUATION

Standard laboratory methods (ANSI S3.19–1974,⁶ ANSI S12.6–1984,²² and ISO 4869 Pt 1–1992⁹) were developed to produce a measurement of attenuation for an optimum-fit condition. Since the late 1970s, researchers in various laboratories around the world¹³ have been investigating the amount of attenuation workers typically receive. They found workers generally received much less attenuation than the optimum-fit laboratory methods predict. The magnitude of the difference was from 22 to 84% less attenuation for the real-world setting than for laboratory setting. Researchers of the ANSI working group have worked with researchers from other laboratories to develop and test laboratory methods that give measurements of hearing protector attenuation, which are more reflective of real-world performance and remain consistent from laboratory to laboratory. The new method provides very consistent interlaboratory results, much more consistent than those possible using the methods of ANSI S3.19–1974.⁶ This latest standard, ANSI S12.6–1997 (B),⁴ provides mean attenuation values that are much lower than optimum-fit attenuation and more in accord with real-world results, while maintaining a reasonable standard deviation.

9 PROBLEMS WITH HEARING PROTECTORS

Comfort, wearability, and durability are just as important, if not more important, than a few decibels more attenuation. Provided that the attenuation is reasonable, human factors issues usually make the difference in HPD selection. Some of these factors include hygiene, discomfort, effects on communication, effect on directional localization and distance of warning sounds, and safety in general. In particular, many workers complain that HPDs compromise their ability to hear fellow workers, public address system announcements, warning and other signals, and auditory cues from their machines (which they may rely on for carrying out their work). This is one of the major reasons for the development of augmented HPDs, which are discussed in Section 12.

10 COSTS OF HEARING PROTECTORS

The cost of hearing conservation by means of personal hearing protection should consider the following factors:

1. Initial cost of muffs and/or plugs
2. Management and administrative costs of ordering, documentation, storage, issuing, fitting, training, and assessment of effectiveness in a hearing conservation program
3. Replacement of the worn parts
4. Education in and encouragement toward the use of hearing protectors, correctly and consistently, using videos, lectures, posters, audiometric feedback, and the like

These costs can be compared with other methods of engineering noise reduction, say for the period of a 5- or 10-year hearing conservation program.

11 REPORTING PROTECTIVE FAILURES

Every employee should learn to be personally responsible for reporting HPD failures or other related noise exposure problems, which may include:

- Damaged HPDs
- Inflammation of the ear that may be due to HPD usage
- Overly compromised hearing of necessary workplace signals or speech
- Changes in conditions of machinery and equipment because of wear or lack of maintenance
- Any change in the perceived noise exposure due to moving of machines, new machines, and/or altered working methods and work practices

Ultimate responsibility for documenting these problems should be given to the health and safety representatives, to foremen and supervisors, and/or to the management staff. Direct and prompt action should be taken to mitigate or correct the failures or problems within the company's noise plan. Of course, reporting protective failures must not affect the worker's social status, job assignment, or compensation in the workplace.

12 AUGMENTED VERSUS CONVENTIONAL PASSIVE HPDs

So-called *conventional* HPDs constitute the vast majority of HPDs, and these devices have been the primary subject of this chapter to this point. These devices achieve attenuation of noise strictly by passive means without the use of dynamic mechanical elements or electronic circuitry and are effective protection against nearly all industrial noises and many military noises, if properly selected and worn. However, due to the very nature of the attenuation that conventional HPDs provide, signals and speech are attenuated no differently than noise of the same frequencies. Furthermore and by design, conventional HPDs reduce noise at the ear solely by passive means, and the attenuation provided is the same regardless of the incident sound pressure level, that is, the devices are *level independent* or *amplitude insensitive*. Although the devices are currently tested at the threshold of hearing using REAT

standards (e.g., ANSI S3.19–1974; Experimenter-Fit in the U.S.⁶), the attenuation achieved at threshold remains the same (or linear) throughout most of the dynamic range of noises normally encountered in industry and other settings. Exceptions include extremely high impulses of noise that may excite the HPD on the human head, an example being the separation of an earmuff cushion from the side of the head as an explosion's blast passes it. It is also noteworthy that most conventional HPDs have spectral attenuation curves that increase (more attenuation) nonlinearly as a function of sound frequency as described above.

A major impetus for the development of augmented HPDs has been the sometimes negative influence that conventional HPDs have on the hearing ability of users.²³ They have often been implicated in compromised auditory perception, degraded signal detection, and reduced speech communication abilities. Depending upon situational demands, these effects can create hazards for the wearer, or at the very least, resistance to use by those in need of hearing protection.

12.1 HPD Effects on Hearing Speech and Signals

Users may reject hearing protection if it compromises their hearing to an extent where sounds no longer appear natural, signals cannot be detected, and/or speech cannot be understood. In some cases, too much attenuation may be provided by an HPD for a particular noise situation, with the concomitant effect that the user's hearing is unnecessarily degraded. In very lay terms. This is commonly referred to as *overprotection*.

Overall, the research evidence on normal hearers generally suggests that conventional passive HPDs have little or no degrading effect on the wearer's understanding of external speech and signals in ambient A-weighted sound pressure levels above about 80 dB and may even yield some improvements with a crossover between disadvantage to advantage between 80 and 90 dB.²³ However, HPDs do often cause increased misunderstanding and poorer detection (as compared to unprotected conditions) in lower sound pressure levels, where HPDs are not typically needed for hearing protection anyway but may be applied for reduction of annoyance. In intermittent noise, HPDs may be worn during quiet periods so that when a loud noise occurs, the wearer will be protected. However, during those quiet periods, the conventional passive HPDs typically reduce hearing sensitivity.

Noise- and age-induced hearing losses generally occur in the high-frequency regions first, and for those so impaired, the effects of HPDs on speech perception are not clear-cut. Due to their already elevated thresholds for mid- to high-frequency speech sounds being further raised by the protector, hearing-impaired individuals are usually disadvantaged in their hearing by conventional HPDs. Although there is no consensus across studies, certain reviews have concluded that sufficiently hearing-impaired individuals will usually experience additional reductions in communication abilities with conventional HPDs worn in noise.²⁴

Conventional passive HPDs cannot differentiate and selectively pass speech or nonverbal signal (or speech) energy versus noise energy at a given frequency. Therefore, conventional HPDs do not improve the speech/noise ratio in a given frequency band, which is the most important factor for achieving reliable detection or intelligibility. Since conventional HPDs attenuate high-frequency sound more than low-frequency sound, thereby attenuating the power of consonant sounds that are important for word discrimination, which lie in the higher frequency range, while also allowing low-frequency noise through, they enable an associated upward spread of masking to occur if the penetrating noise levels are high enough.

Since some of the high-frequency binaural cues (especially above about 4000 Hz) that depend on the pinnae are altered by HPDs, judgments of sound direction and distance may be compromised. Earmuffs, which completely obscure the pinnae, radically interfere with localization in the vertical plane and also tend to cause horizontal plane errors in both left-to-right and front-to-back judgments.²⁴ Earplugs may result in some front-back judgment errors but generally cause fewer localization problems than muffs, although exceptions do exist.

The safety professional often faces a dilemma in selecting HPDs for the workforce that provides adequate attenuation for the noise threat at hand, but also that does not provide so much attenuation that the worker cannot hear important signals and/or speech communications. This is the dilemma of *underprotection* versus *overprotection*.

To reduce worker complaints, and to some extent mitigate the underprotection versus overprotection dilemma, certain features have been developed and integrated into HPDs, as follows.

12.2 Uniform (Flat) Attenuation HPDs

Conventional HPDs generally increase attenuation profile as a function of frequency and, therefore, create a frequency imbalance from the listener's perspective. This is because the relative amplitudes of different frequencies are heard differently than they would be without the HPD, and, thus, broadband acoustical signals are heard as spectrally different from normal; in other words, usually as more *bassy*. Thus, the spectral quality of a sound is altered, and sound interpretation, which is important in certain jobs (e.g., machining, mining, and performing music), that relies on auditory inspection, may suffer as a result.

In an attempt to counter these effects, flat- or uniform-attenuation HPDs such as the ER-15 Musician's earplug or the ER-20 Hi-Fi earplug have been developed.²³ These devices utilize acoustical networks to provide essentially flat attenuation over the range of frequencies from 125 to 8000 Hz (see Fig. 4).

12.3 Level-Dependent HPDs

Level-dependent (also sometimes called *amplitude-sensitive*) HPDs are designed to intentionally change their attenuation characteristics as the incident noise level changes (increasing attenuation as noise level

Figure 4 Attenuation characteristics of two flat-attenuation earplugs and for standard premolded, fiberglass, and foam earplug. (From Berger.¹)

increases). Such devices may be passive (relying on acoustical networks or mechanical valves for their unique attenuation characteristics) or electronic. While most of these devices are based on earmuff designs (e.g., the EAR Ultra 9000), a few level-dependent earplugs exist (e.g., the Gunfender and the U.S. Army's Combat Arms Earplug). Typically, these devices offer little or no attenuation at low to moderate noise levels; however, as ambient noise levels increase, their attenuation increases to some maximum level. The Army's Combat Arms Earplug reduces impulse noise levels of a howitzer (170 dB Peak to an acceptable level) while permitting normal speech and commands to be understood.

Passive Level-Dependent HPDs In passive level-dependent HPDs, a valve or sharp-edged orifice provides a controlled leakage path into the HPD. At low noise levels, the passive attenuation of the device behaves as that of a *leaky protector*, offering minimal attenuation below about 1000 Hz. This minimal attenuation is all that is available to protect the wearer's hearing at sound pressure levels below about 110 dB. Since such devices are intended to be used primarily in intermittent impulsive noise, this should not be a problem as long as the *off* periods are relatively quiet (e.g., below about an A-weighted sound pressure level of 85 dB). At elevated sound pressure levels (above about 110 to 120 dB, as might occur during a gunshot), the flow through the orifice changes from laminar to turbulent, effectively closing the orifice, thus increasing the attenuation of the device. An additional advantage is that some orifice-based devices offer roughly flat attenuation.²⁵

Electronic Level-Dependent HPDs These battery-powered electronic HPDs are typically earmuff based and incorporate a microphone and output-limiting

Figure 5 Example operating characteristics of an electronic level-dependent sound transmission earmuff (input is the ambient A-weighted sound pressure level in the environment and output is the earphone output).

amplifier to transmit external sounds to earphones mounted within the earcups. The electronics can be designed to pass and boost only certain sounds, such as the critical speech band or critical warning signal frequencies. Typically, the limiting amplifier maintains a predetermined (in most cases user-adjustable) gain, often limiting the earphone output to about an A-weighted sound pressure level of 82 to 85 dB, unless the ambient noise reaches a cutoff A-weighted sound pressure level of 115 to 120 dB, at which point the electronics cease to function (Fig. 5). At this point, the device essentially becomes a passive HPD.

Ideally, a level-dependent sound transmission HPD should exhibit flat frequency response and distortion-free amplification (without spurious electronic noise) across its passband, as well as high signal-to-noise (S/N) ratios at levels below its predetermined cutoff level. The cutoff level itself should be safe (to ensure that transmitted sound does not overexpose the wearer), achieved quickly (i.e., with little or no delay), and have a sharp attenuation transition without transients or oscillations. The passband of the electronics should be adequate to accommodate desired signals but not so wide as to pass unnecessary and undesirable noise to the listener. The external microphones (two, one for each ear to permit dichotic listening to aid in sound localization) should be minimally affected by wind or normal movement of the head. Such devices have the potential for improving the hearing of *hearing-impaired* listeners in quiet or moderate noise levels, acting much like a user-adjustable hearing aid. However, normal-hearing listeners may not realize similar benefits due to the potential for the residual electronic noise to mask desired signals. Like their passive counterparts, some of these devices are well suited for impulsive noise, but less so for sounds with long on durations, which can produce objectionable distortions.

Two example studies on electronic level-dependent earmuffs^{26,27} have, respectively, demonstrated that (1)

several example devices exhibited adequate protection against most gunfire noise exposures, and (2) user-preferred settings of the volume control did not result in an appreciable increase in noise exposure dose over that experienced with the electronics turned off. More research on level-dependent HPDs is needed on the issues of protection from sharp transient impulses, such as high-caliber weapons and pile drivers, and on the efficacy of these devices in improving hearing ability in low-to-moderate level noises. On the issue of testing these HPDs against sharp impulse noise of very high levels, REAT testing is not applicable, so acoustical manikins exposed to noises produced by special apparatus for producing shock waves are necessary.^{28,29}

12.4 Active Noise Reduction (ANR) HPDs

Active noise reduction relies on the principle of destructive interference of equal amplitude, about 180° out-of-phase sound waves at a given point in space; in the case of hearing protectors, the cancellation is established at, or very near, the outer ear. ANR has been incorporated into two types of at-the-ear systems: (1) those designed solely for hearing protection and (2) those designed for one- or two-way communications. Both types are further dichotomized into open-back (or supraaural) and closed-back (or circumaural earmuff) variations. In the former, a lightweight headband connects ANR microphone/earphone assemblies that are surrounded by foam pads that rest on the pinnae. In that there are no earmuff cups to afford passive protection, the open-back devices provide only active noise reduction. If there is an electronic failure, no protection is provided by the open-back device. Closed-back devices, which represent most ANR-based HPDs, are typically based on a passive noise-attenuating earmuff that houses the ANR transducers and, in some cases, the ANR signal processing electronics. If backup attenuation is needed from an ANR HPD in the event of an electronic failure of the ANR circuit, the closed-back HPD is advantageous due to the passive attenuation established by its earcup.

Analog and Digital ANR HPDs Detailed descriptions of the technology behind ANR electronic feedback/feedforward control systems are beyond the scope of this chapter but may be found in Casali and Robinson.³⁰ Basically, in a typical analog device, a closed-loop, feedback system is used that receives input from a sensing microphone that detects the noise that has penetrated the passive barrier posed by an earmuff. The signal is then fed back through a phase compensation filter, which reverses the phase, to an amplifier that provides the necessary gain, and finally is output as an *antinoise* signal through an earphone loudspeaker to effect cancellation inside the earcup. Digital technology, with its advances in speed, power, reliability, and miniaturization of signal processing components, has demonstrated strong promise for improving the capabilities of ANR-based HPDs, particularly in regard to precise tuning of the control system via software for optimizing the cancellation of specific sound frequencies.

Figure 6 Attenuation of the NCT PA-3000 closed-back ANR headset. (From Casali and Robinson.³³)

Due to the phase shifts that can be attributed to transducer (i.e., microphone, earphone) location differences, as well as the possibility of throughput delays in signal processing, establishing the correct phase relationship of the cancellation signal and noise becomes more difficult as the bandwidth of the noise increases; therefore, ANR has typically been most effective against *low-frequency* noise.

In certain types of noises, especially those characterized by high overall levels and/or frequency content that is heavily skewed toward frequencies of less than 1000 Hz, ANR-based hearing protectors may offer some warning signal detection advantages over HPDs with weaker low-frequency attenuation; however, these improvements are likely to be very user- and HPD-specific.³¹ Part of the reason for the potential advantage is that in severe low-frequency noise, the ANR may serve to prevent the upward spread of noise masking into the warning signal's bandwidth.

ANR HPD Attenuation and Testing/Labeling Issues At present, standardized attenuation data and NRR ratings are not available for ANR hearing protectors. Microphone-in-real-ear (MIRE) testing (e.g., using ANSI S12.42-1995³²) can be used to measure the passive (ANR off) and total (ANR on) attenuation of the device. The active component of the attenuation can then be computed using the following relationship, with each term measured in decibel attenuation:

$$\text{Active component} = \text{MIRE total} - \text{MIRE passive}$$

REAT or MIRE testing can be used to quantify, for performance testing purposes, the passive component

of the total attenuation, but the choice of method can affect the data. For example, MIRE attenuation at low frequencies is lower than REAT attenuation due to the physiological noise masking effects on occluded thresholds that occur in REAT testing. In addition, MIRE, unlike REAT, does not account for the bone conduction flanking path. Finally, passive attenuation is often decreased in the middle frequencies (from about 1000 to 3000 Hz) when the ANR circuit is turned on (i.e., the electronics produces and/or amplifies noise, which increases the noise level under the protector).

Typical REAT and MIRE attenuation for an earmuff-based ANR HPD is shown in Fig. 6. Readily apparent in the figure is the difference between the MIRE and REAT attenuation at 125 and 250 Hz. This difference is likely due to physiological noise masking the test stimulus during the REAT test. Also evident in the figure is the slight reduction in total attenuation at 1000 and 2000 Hz when the ANR device is turned on. In general, the depicted ANR muff has enhanced low-frequency attenuation and good mid range and high-frequency performance as well. However, even a well-designed large-volume ANR earmuff such as the one in Fig. 5 cannot typically outperform, on a purely attenuation basis, a well-fitted (and less expensive) foam earplug covered by a quality passive earmuff.²³ Consequently, some manufacturers of ANR-based devices distinguish their products by features and parameters other than attenuation performance, such as comfort and frequency response.

Current ANR HPD Applications Although ANR devices cannot currently be sold in the United States

under EPA labeling regulations as *hearing protectors* (except as to their passive attenuation only) due to the lack of appropriate ANR testing standards and labeling regulations, they are being used for various purposes in both the public and private sector. ANR headsets are sold to reduce noise annoyance (airline passenger and personal stereo headsets), as communications headsets for commercial, military, and civilian aviation, and used to combat severe noise environments in the military (particularly in armored vehicles). Special-purpose ANR devices are also (or have been) commercially available for telephone operators and telemarketers, to reduce patient noise exposure in magnetic imaging machines, and even to reduce siren noise for emergency vehicle crews. There is some disagreement in the hearing protection scientific community as to the potential for the application of ANR HPDs to industrial noise markets (for which low-frequency noise is *not* the norm) and, therefore, whether an NRR-like rating is really necessary.

12.5 Adjustable Attenuation HPDs

To help overcome the problem of overprotection in moderate noise environments, earplug designs have recently been developed that allow the user some level of control over the amount of attenuation achieved. These devices incorporate a leakage path that is adjustable via the setting of a valve that obstructs a tunnel or "vent" cut through the body of the plug, or via selection from a choice of available filters or dampers that are inserted into the vent.

The Dutch Ergotec Varifone is an example of an adjustable-valve design that is constructed from an acrylic custom-molded impression of the user's ear canal. According to the manufacturer's data, below 500 Hz the attenuation adjustment range is approximately 20 to 25 dB, with a maximum attenuation of about 30 dB at 500 Hz. At higher frequencies, the range of adjustment decreases, while the maximum attenuation attainable increases slightly. An example of a selectable-damper design is the Sonomax SonoCustom, manufactured in Canada. The Sonomax device has a variety of different attenuation dampers that provide the opportunity for discretely variable attenuation in a single device. Furthermore, the SonoCustom HPD is sold as a system with a probe tube microphone test apparatus that verifies the amount of attenuation achieved via MIRE techniques on each user as they are fit with the product.

There are two important distinctions between passive adjustable-attenuation HPDs and passive level-dependent HPDs discussed earlier. The former require user setting to effect attenuation changes, and the attenuation, once selected, is essentially independent of incident sound pressure level. Level-dependent devices, on the other hand, react automatically to changes in incident sound pressure levels, and the user typically has no control over the change in attenuation.

The adjustable attenuation class of HPD affords much flexibility in product design/development in that they can be fitted with *modular* augmentations, and

this is a major advantage in that these relatively expensive and personalized (i.e., custom- or semi-custom-molded) earplugs can be adapted to changing user needs and different noise environments. Filter-based devices can be tuned for specific environments or tuned to pass speech or other critical bands necessary for specific jobs. As this technology matures, the potential exists that additional electronic augmentations can also be incorporated into the devices (e.g., noise suppression, electronic filtering, closed-loop attenuation control, hearing assistive circuits, automatic gain control, etc.). This capability offers promise for improving the hearing ability of HPD users in noise environments over that which would be attained with conventional HPDs alone. Furthermore, there is much promise for "tuning" this type of HPD to optimize its characteristics for the individual user.

Ashland, Oregon

1 INTRODUCTION

Millions of people throughout the world are exposed to hazardous levels of noise. Because of lack of knowledge or lack of concern, a substantial portion of those exposed are losing their hearing. Occupational noise is not adequately dealt with by marketplace incentives. Worker compensation for hearing loss, at least in the United States, is relatively insignificant as a motivation for noise control. If workers' hearing is to be conserved, it is almost always up to government bodies to inform and regulate employers through necessary standards and regulations. It is important for safety and health professionals to be informed about the standards and regulations that apply to their companies in order to protect employees.

The regulatory process is not a simple one since several weighty decisions need to be made, including the amount of hearing and the percentage of the noise-exposed population to be protected. Thus it is not surprising that standards and regulations for noise exposure vary among the different nations, although recent trends are toward uniformity. Noise exposure regulations in the United States, however, seem to be lagging behind the other industrialized nations, both in terms of the degree of protection and the implementation of noise control measures.

2 NEED FOR STANDARDS AND REGULATIONS RELATED TO OCCUPATIONAL NOISE

In the United States, an estimated 9 million workers are exposed to average A-weighted sound pressure levels of 85 dB and above. The number of noise-exposed workers in various types of occupations is described in Table 1. Although these data are now more than 20 years old (with the exception of mining), no surveys

Table 1 Number of American Workers Exposed to A-Weighted Sound Pressure Levels of 85 dB or above

Sector	Number of Workers
Agriculture	323,000
Mining	218,400
Construction	513,000
Manufacturing and utilities	5,124,000
Transportation	1,934,000
Military	976,000
Total	9,088,400

of noise exposure have effectively replaced them. One could hope that noise control programs could have reduced these numbers, but there is little evidence to that effect in the United States.

Table 2 shows the noisiest types of U.S. manufacturing industries stated in terms of Standard Industrial Code (SIC), arranged in descending order according to the percentage of workers exposed to A-weighted sound pressure levels above 90 dB. Although this ranking is based on data from U.S. industries, the relative noise hazards of other industries throughout the world is likely to be similar.

The reader should bear in mind that the information given in Tables 1 and 2 is not sufficiently conservative according to more recent damage–risk criteria, which show that a certain percentage of workers will incur material hearing impairment at daily average exposure levels below 85 dB (the criterion used in Table 1) and well below 90 dB (the criterion used in Table 2).

3 TERMINOLOGY

In the field of occupational noise, the terms *regulation*, *standard*, and *legislation* are often used

interchangeably, even though technically they may have slightly different meanings. In the United States, a regulation is a rule or order prescribed by a government authority and is usually more formal than a standard. A standard is a codified set of rules or guidelines, much like a regulation, but can be developed under the auspices of a consensus group, such as the International Organization for Standardization (ISO) or in the United States the American National Standards Institute (ANSI). Legislation consists of laws prescribed by legislating authorities or by local governing bodies.

In some countries national standards are called *legislation*. Some official bodies use the terms standards and regulations as well. The European Union (EU) issues *directives*. All members of the European Community needed to "harmonize" their noise standards (regulations or legislation) with the 1986 directive on occupational noise exposure by the year 1990.⁵ This means that the noise standards and regulations of the member countries had to be at least as protective as the EU's directive. In 2003 the EU issued an updated directive for noise exposure⁶ with which the member nations must comply no later than February 2006.

Some nations have a *code of practice*, which is somewhat less formal. For example, the Australian national standard for occupational exposure to noise consists of two short, mandatory paragraphs, followed by a 35-page code of practice, which provides practical guidance on how the standard should be implemented. Codes of practice usually do not have the legal force of regulations or legislation.

Another term that is used occasionally is *recommendation*, which is more like a guideline than a mandatory rule and is not enforceable. Examples of recommendations issued by a U.S. governmental body would be criteria developed by the National Institute for Occupational Safety and Health (NIOSH),^{7,8} which are often considered recommendations for "best practice."

4 CONSENSUS STANDARDS

At least in the United States, the advent of federal standards for occupational noise exposure was preceded by a series of consensus standards, issued by such organizations as the American Standards Association (the predecessor of ANSI), the National Research Council Committee on Hearing and Bioacoustics (CHABA), and the Intersociety Committee,⁹ a group comprised of members from several professional organizations concerned with noise and hearing. Although these bodies reflected an ever increasing level of knowledge by the professional community, there was a need for uniformity. The U.S. federal government satisfied that need with the promulgation of a noise standard in 1969¹⁰ under the authority of the Walsh-Healey Contracts Act of 1935. The same is happening currently in Europe under the direction of the European Union. In addition to ANSI, several international consensus organizations are currently active in noise standardization, particularly the ISO and the International Electrotechnical Commission (IEC). These organizations have been involved in

the standardization of criteria for exposure to noise, as well as standards for instruments and measurement methodologies.

The ISO's technical committee TC43, Acoustics, is made up of members from 27 countries. ISO Subcommittee SC1, Noise, is primarily concerned with noise exposure, emission, and measurement, as well as hearing conservation and machinery noise.

One of the most widely used noise standards is ISO 1999, Acoustics: Determination of Occupational Noise Exposure and Estimate of Noise-Induced Hearing Impairment,¹¹ which has a counterpart in the United States as ANSI S3.44.¹² Both of these standards may be used to predict the amount of hearing loss expected to occur in various centiles of the exposed population at various audiometric frequencies as a function of exposure level and duration, age, and sex.

5 DAMAGE-RISK CRITERIA

The term *damage-risk criteria* refers to the risk of hearing impairment from various levels of noise. Many factors enter into the development of these criteria and standards in addition to the data describing the amount of hearing loss resulting from a certain amount of noise exposure. There are both technical and policy considerations operating in the development of criteria and their application to standards and regulations.

The following questions are good examples of policy considerations: What proportion of the noise-exposed population should be protected, and how much hearing loss constitutes an acceptable risk? Should we protect even the most sensitive members of the exposed population against any loss of hearing, or should we protect only against a compensable hearing handicap? The answers to these questions are directly related to the hearing loss formula that is used, and different governmental bodies and consensus organizations have varied widely in their selections.

In earlier years, regulatory decisions were made that allowed substantial amounts of hearing loss as an acceptable risk. The most common definition used to be an average hearing threshold level (or "low fence") of 25 dB or greater at the audiometric frequencies 500, 1000, and 2000 Hz. Since that time, the definitions of *hearing impairment* or *hearing handicap* have become more restrictive, with different nations or consensus groups advocating different definitions. For example, one U.S. government agency now uses a 25-dB average at 1000, 2000, and 3000 Hz,⁴ and another uses the same low fence averaged over the frequencies 1000, 2000, 3000, and 4000 Hz.⁸ Other definitions may incorporate a low fence of 20 or 30 dB and may include a different frequency combination or a broader range of frequencies.

In general, as definitions include higher frequencies and lower fences or hearing threshold levels, the acceptable risk becomes more stringent, and a higher percentage of the exposed population will appear to be at risk from given levels of noise. If there is to be no risk of any hearing loss from noise exposure, even in the more sensitive members of the exposed population, the permissible 8-h exposure limit would

have to be as low as an A-weighted sound pressure level of 75 dB. In fact, the EU has established an equivalent A-weighted sound pressure level (L_{eq}) of 75 dB as the level at which the risk is negligible, and this level has also been put forward as a goal for Swedish production facilities.¹³

Overall, the prevailing thought on this subject is that it is acceptable for a noise-exposed workforce to lose a small amount of hearing, but not too much. As for how much is too much, there is no consensus at this time. In all probability, most nations draft standards and regulations that attempt to keep the risk at a minimum level while taking technical and economic feasibility into account, but without coming to consensus on such matters as the frequencies, fence, or percentage of the population to be protected.

6 PRESENTING THE DAMAGE-RISK CRITERIA

Criteria for noise-induced hearing loss may be presented in either of two ways: noise-induced permanent threshold shift (NIPTS) or percentage risk. NIPTS is the amount of permanent threshold shift in decibels remaining in a population after subtracting the threshold shift that would occur "normally" from causes other than occupational noise. The percentage risk is the percentage of a population with a given amount of noise-induced hearing impairment *after* subtracting the percentage of a similar population *not* exposed to occupational noise that would exceed that same impairment due to aging and other causes. This concept is sometimes called *excess risk*. Unfortunately, neither method is without problems.

The problem with using NIPTS alone is that it is difficult to summarize the effects of noise on hearing. The data are usually set out in a large table showing noise-induced threshold shift for each audiometric frequency as a function of noise level, years of exposure, and population centile. The concept of percentage risk is more attractive because it uses single numbers and appears to be easy to understand. But the problem with percentage risk is that it can vary enormously, depending on a number of factors, particularly the height of the hearing threshold level fence and the frequencies used to define hearing impairment (or handicap).

With both methods, the user needs to be sure that the exposed and nonexposed populations are well matched for such factors as age, nonoccupational noise exposure, and the fence and audiometric frequencies used to define hearing impairment (or handicap). For example, ISO 1999 offers two databases for use in predicting hearing loss from noise. Database A presents hearing threshold data from a European population, which has had minimal noise exposure. Database B gives hearing levels of a U.S. population with greater amounts of nonoccupational noise exposure plus some small amounts of occupational exposure. Both databases are at least 40 years old at this time, and nowadays it is difficult to find subjects in industrialized nations that have had no exposure to noise.

Table 3 Example of a Population at Risk from Noise Exposure

A-weighted noise exposure level: 90 dB
Sex: Male
Age: 50
Years of exposure: 30
Nonnoise population: Database A
Frequencies: average at 1000, 2000, 4000 Hz
Fence: 27 dB
Risk from aging: 3%
Risk from noise + aging: 16%
Percent risk: 13%

Source: From Ref. 11.

Table 4 Example of a Population at Risk from Noise Exposure

A-weighted noise exposure level: 90 dB
Sex: Male
Age: 60
Years of exposure: 40
Nonnoise population: Database A
Frequencies: average at 1000, 2000, 4000 Hz
Fence: 27 dB
Risk from aging: 15.5%
Risk from noise + aging: 35%
Percent risk: 19.5%

Source: From Ref. 11.

Table 3 shows an example of the percentage risk method taken from ISO 1999, Annex D.¹¹ According to the ISO data and method, the risk in a male population due to noise at an average A-weighted sound pressure level of 90 dB after 30 years of exposure is 13%, using the frequencies 1000, 2000, and 4000 Hz and a fence of 27 dB.

Using the same data and method, but changing just a few parameters, the risk becomes 19.5%, as in Table 4. By examining hearing impairment at age 60 instead of age 50, with 40 years of exposure instead of 30, the risk has been increased considerably.* Moreover, the risk from aging alone has increased from 3 to 15.5% within 10 years.

Likewise, any change in the level of the fence or the selected frequencies would also change the outcome in terms of percentage risk. It is up to the policymakers to decide these parameters, as well as the predicted duration of noise exposure (a working lifetime of 30 or 40 years), in determining how much loss is to be prevented.

7 NOISE STANDARDS OF VARIOUS NATIONS

Table 5 gives some of the main features of the noise exposure standards of several nations. Most of the information is current as of this publication, but some

*These figures are slightly different from those that would be obtained using the example in ISO Annex D. In the ISO example, the user makes a small adjustment to the NIPTS values, whereas it is more correct to make this adjustment to the hearing loss from aging, as has been done here.

Table 5 Permissible Exposure Limits (PEL), Exchange Rates, and Other Requirements for Noise Exposure According to Nation

Nation Date (if available)	PEL L_{av} (8-h) (A-weighted average sound pressure level in dB)	Exchange Rate (dB)	L_{max} (dB) L_{peak} (dB)	Level Eng. Control (A-weighted average sound pressure level in dB)	Level Audio. Test (A-weighted average sound pressure level in dB)	Comments

^aA-weighted sound pressure level.^bC-weighted sound pressure level. No designation presumes unweighted.

Note 1. Argentine standard 295/2003 states that no work is allowed for sound pressure levels greater than 135 dB even for workers wearing hearing protectors.

Note 2. Each of the Australian states and territories has its own legislation for noise. All have now adopted the 8-h A-weighted L_{eq} of 85 dB and most have a standard of 140-dB peak C-weighted sound pressure level for impulses.Note 3. There is some variation among the individual Canadian provinces: Ontario and Quebec use an A-weighted sound pressure level of 90 dB with a 5-dB exchange rate; Alberta, British Columbia, New Brunswick, Newfoundland, Nova Scotia, Saskatchewan, and Yukon use 85 dB with a 3-dB exchange rate; and Northwest Territories uses 85 dB with a 5-dB exchange rate. All require engineering controls to the level of the PEL, at least for new equipment, processes, or worksites. Manitoba requires certain hearing conservation practices above an A-weighted level of 80 dB, hearing protectors and training on request above 85 dB, and engineering controls above 90 dB. The federal standard, effective July 1991, has no requirements for L_{max} or L_{peak} .

Note 4. Chilean standard DS 594/99 of April 2000 requires a maximum C-weighted sound pressure level of 95 dB for an 8-h exposure to impulse noise, measured at the worker's ear using a 3-dB exchange rate.

Table 5 (continued)

Note 5. In Denmark, a correction of 5 dB must be added to the measured A-weighted sound pressure level if the noise is impulsive. A noise is defined as impulsive if the peak A-weighted or C-weighted sound pressure level (on the peak-hold setting) exceeds 115 dB more than once per minute. The person measuring the noise has the option of using either A- or C-weighting.

Note 6a. European Union (Directive 2003/10/EC)⁶ puts forward three exposure values: an A-weighted exposure limit value of L_{eq} 87 dB and a peak C-weighted sound pressure level of 140 dB; an "upper action" A-weighted sound pressure level of 85 dB and a peak C-weighted sound pressure level of 137 dB; and a "lower action" A-weighted sound pressure level of 80 dB and a peak C-weighted sound pressure level of 135 dB. The attenuation of hearing protectors may be taken into account when assessing the exposure limit value, but not for requirements driven by the upper and lower action values. At no time shall employees' noise exposures exceed the exposure limit value. When exposures exceed the upper action level, the employer must implement a program of noise reduction, taking into account technology and availability of control measures.

Note 6b. EU continued.⁶ Hearing protectors must be made available when exposures exceed the lower action A-weighted sound pressure level of 80 dB. Hearing protectors must be used by workers whose exposures equal or exceed the upper action value of 85 dB. Audiometric testing must be available to workers whose exposures exceed the upper action value, and when noise measurements indicate a risk to health these measures must be available at the lower action value.

Note 7. The German standard (UVV Lärm-1990) states that it is not possible to give a precise limit for the elimination of hearing hazard and the risk of other health impairments from noise. Therefore the employer is obliged to reduce the noise level as far as possible, taking technical progress and the availability of control measures into account.

Note 8. India: Recommendation.

Note 9. The Netherlands' noise legislation requires engineering noise control at an A-weighted sound pressure level or 85 dB "unless this cannot be reasonably demanded." Hearing protection must be provided above 80 dB and workers are required to wear it at levels above 90 dB.

Note 10. Norway requires an A-weighted PEL of 55 dB for work requiring a large amount of mental concentration, 70 dB for work requiring verbal communication or great accuracy and attention, and 85 dB for other noisy work settings. Recommended limits are 10 dB lower. Workers exposed to average A-weighted sound pressure levels greater than 85 dB should wear hearing protectors.

Note 11. In accordance with the new EU directive, Sweden uses the same 85-dB upper and 80-dB lower exposure values but reduces the limit value from 87 to 85 dB. The C-weighted peak sound pressure levels are also 135 for the upper, lower, and limit values, which is more conservative than the EU directive. In addition, Sweden adds a requirement for a maximum A-weighted sound pressure level (presumably for continuous noise) of 115 dB.

Note 12. These levels apply to the OSHA noise regulation¹⁶ covering workers in general industry and maritime. The U.S. military services require standards that are somewhat more stringent. The U.S. Air Force and the U.S. Army both use an 85-dB PEL and a 3-dB exchange rate.

standards may have been recently revised. Readers are advised to consult the newest versions of the individual nations' standards.

8 OTHER FEATURES OF NATIONS' NOISE STANDARDS

In addition to their requirements to protect workers against hearing loss, several nations include provisions for preventing other adverse effects of noise. Some nations state the need to protect against the extraauditory effects of noise in their regulations. Both the EU directive and the German standard acknowledge

that workplace noise involves a risk for the health and safety of workers beyond hearing loss, but that current scientific knowledge of the extraauditory effects does not enable precise safe levels to be set.

The Norwegian standard includes a requirement that noise levels must not exceed an A-weighted sound pressure level of 70 dB in work settings where speech communication is necessary. The German standard advocates noise reduction for the prevention of accident risks, and both Norway and Germany require a maximum A-weighted noise level of 55 dB to enhance concentration and prevent stress during mental tasks.

Some countries have special noise standards for different kinds of workplaces. For example, Finland and the United States have noise standards for commercial vehicle cabs, and Germany and Japan specify noise levels for offices. Others include noise as one of many regulated hazards in a particular process. Still other standards apply to specific types of equipment or machines, such as air compressors, chain saws, and construction equipment.

In addition, some nations have promulgated separate standards for hearing protection devices (e.g., the EU, Netherlands, and Norway) and for hearing conservation programs (e.g., France, Norway, Spain, Sweden, and the United States).

Some nations use innovative approaches to attack the occupational noise problem. For example, the Netherlands has a separate standard for newly constructed workplaces, and Australia and Norway give information to employers for instructing manufacturers to provide quieter equipment.

There is little information about the degree to which these standards and regulations are enforced. Some specify that employers "should" take certain actions (as in codes of practice or guidelines), while most specify that employers "shall." Standards that use "shall" are more apt to be mandatory, but individual nations vary widely in their ability and inclination to enforce. Even within the same nation, enforcement of occupational noise standards may vary considerably with the government in power.

CHAPTER 33

HEARING CONSERVATION PROGRAMS

John Erdreich
Ostergaard Acoustical Associates
West Orange, New Jersey

1 INTRODUCTION

Hearing conservation programs have evolved from their original purpose of simply screening employee hearing. With increasingly sophisticated analyses of growing databases of employee audiometric data, of more detailed exposure records, and industry strategies to control noise exposure, the hearing conservation program has become the basis not only by which to protect worker hearing, but it is also a powerful tool with which to limit employer exposure to liability for nonoccupationally caused hearing impairments. Hearing conservation programs are, in essence, an educational tool for both the employer and the employee.

1.1 Purpose of Hearing Conservation Programs

The essential components of a hearing conservation program (HCP) are as follows:

- Selection of a “key person” with responsibility and authority to coordinate all facets of the HCP for both worker and employer.
- Education of both parties regarding the effects of noise exposure on hearing.
- Annual audiometric screening of noise-exposed employees.
- Identification of locations and processes contributing to noise exposures.
- A program of noise control where exposures exceed a selected criterion level.
- Selection of the criterion noise exposure acceptable to management.
- Annual reviews of hearing losses to identify cause.

1.1.1 Protection of Employee Hearing Early hearing conservation programs were implemented in several industries following World War II. Primary among these were aircraft, petrochemical, and some railroads. In 1950, Kryter¹ published the original version of his monograph that described the relation between noise exposure and occupational hearing loss. This was further clarified by Glorig et al.² and by Burns and Robinson³ in their studies of noise in American and British industry.

By the mid-1960s it was clear that noise-induced hearing loss (NIHL) was a serious problem and that workers needed to protect their hearing. In the United States regulations were promulgated mandating

acceptable noise exposures. At this writing, the United States, the European Union, and many other countries have promulgated similar regulations to protect and conserve worker hearing.

1.1.2 Limitation of Employer Liability Although early in the twentieth century there was little recourse an employee had to be compensated for occupational injuries or diseases, major changes began to evolve after World War II. In 1948 New York State workman’s compensation law was expanded to include coverage for noise-induced hearing loss (*Slawinsky vs. J. H. Walters and Company*). In the period between 1948 and 1962 other states adopted similar positions in which noise-induced hearing loss, although it develops over time, was considered a compensable occupational injury.

Workman’s compensation laws set schedules for compensation for occupational injuries and diseases. The employer is protected, to a degree in the United States, by its insurance coverage through the workers compensation system. However, for noise-induced hearing loss the employee can overcome the limited compensation payments if negligence on the part of his employer can be demonstrated. In that case, the injury is treated under tort law and is not adjudicated under the workman’s compensation system. Nor is it likely covered by the employer’s insurance. A comprehensive hearing conservation program will not only protect employee hearing but also will demonstrate that there is no negligence. Furthermore, it will document the hearing levels and progression of hearing impairment, if any, in the employee and others with similar exposures. This record is the best defense in tort litigation.

1.2 Relation of the Hearing Conservation Program (HCP) to Regulations

1.2.1 Occupational injury compensation In the United States, a system of compensation for occupational injury has developed since the midtwentieth century. Workman’s compensation programs attempt to provide for this compensation in an environment that creates a buffer between the employee and the employer by establishing a uniform procedure for the injured employee to receive compensation for an injury. These programs impose three general requirements upon the claimant:

The existence of an injury must be established.
Occupational causality must be demonstrated.
Economic impact of the injury must be determined.

The existence of a hearing impairment is evaluated in the annual audiometric screening that is part of the HCP. This will be discussed subsequently.

For a determination of occupational causality for a noise-induced hearing impairment, demonstration of employee noise exposure sufficient to produce the measured impairment is required. Records of sound surveys conducted as part of the HCP can establish, in conjunction with an employee work history, the noise exposure of the individual during the period of employment. In this regard, a proper HCP provides a strong basis for adjudicating a claim for compensation for an occupational hearing impairment. An otologic examination is also recommended to preclude the existence of hearing impairments arising from nonoccupational causes.

Some jurisdictions require that the employee comply with the requirements of the HCP implemented by the employer. If the employer can demonstrate that the employee has not properly used the hearing protection provided, then the claim may be disallowed. For example, the New Jersey Workman's Compensation Statute (34:15-35.22)⁴ states:

No compensation shall be payable for loss of hearing caused by hazardous noise...if an employer can properly document that despite repeated warnings, an employee willfully fails to properly and effectively utilize suitable protective device or devices provided by the employer capable of diminishing loss of hearing due to occupational exposure to hazardous noise.

Economic impact of a hearing impairment is assumed in all American workman's compensation regulations, although the schedule of compensation varies by jurisdiction and from federal to state plans. This is unrelated to the facts of exposure documented in the HCP.

1.2.2 Torts Although a system of compensation exists for occupational NIHL, the schedule of compensation is limited and does not protect the employer from litigation under the tort statutes. Generally, if the employee can demonstrate negligence on the part of the employer or a defect on the part of the manufacturer of the tools used in the course of employment, then it is possible to claim compensation unrestricted by the schedules set forth in the workman's compensation statutes.

In addition to employee audiometric data and noise surveys, HCP documentation should include company memoranda that describe the history of the HCP as well as the individuals responsible for its implementation. These are important instruments in the defense of these claims. For companies with several facilities the HCP should follow similar guidelines at each location to establish that corporate management has committed to the safety of its employees.

1.2.3 Exposure Limitation Permissible employee noise exposure in the United States is promulgated under the Occupational Safety and Health Act

(OSHA), CFR 1910.29.⁵ In 1981 a dual limit was established by the Hearing Conservation Amendment to the act that established a threshold exposure at which hearing conservation is mandatory (the action level) and a higher threshold (the permissible exposure level, PEL), which defined the limit of exposure. These criteria are based on a 5-dB exchange rate (every 5-dB increase in level requires a halving of exposure time) and an 8-h exposure (Table 1).

Permissible time of exposure (t , in hours) at any level may be calculated as

$$t = \frac{8 \text{ h}}{2^{(L-90)/5}}$$

where L is the level of the sound to which the employee is exposed, 5 represents the exchange rate, and 90 is the 8-h PEL. Similar calculations may be carried out for a 3-dB exchange rate by replacing the 5 with 3.

Table 1 Allowable Time (T) of Exposure in Minutes for 5- and 3-dB Exchange Rate at Different Levels

Level	T at 5 dB	T at 3 dB
80	1920	4838
81	1671	3840
82	1455	3048
83	1267	2419
84	1103	1920
85	960	1524
86	836	1210
87	728	960
88	633	762
89	551	605
90	480	480
91	418	381
92	364	302
93	317	240
94	276	190
95	240	151
96	209	120
97	182	95
98	158	76
99	138	60
100	120	48
101	104	38
102	91	30
103	79	24
104	69	19
105	60	15
106	52	12
107	45	9
108	40	8
109	34	6
110	30	5
111	26	4
112	23	3
113	20	2
114	17	2
115	15	1

Noise dose (D) is defined in terms of the 90 dB A-weighted sound pressure level 8-h limit that represents (OSHA) 100% dose. For a given exposure and duration (T_i) the dose may be calculated as

$$D = \frac{T_i}{t} \times 100$$

$$= \frac{2^{(L-90)/5}}{8} \times T_i \times 100$$

Doses comprised of exposures at different levels are calculated by adding the individual doses. The OSHA action level is simply 50% of the 5 dB-exchange dose.

In some cases the employee exposure is reported in terms of the time weighted average level. This is the 8-h exposure equivalent to the calculated dose. Time weighted average is calculated as

$$D = \left(\frac{T_1}{t_1} + \frac{T_2}{t_2} + \frac{T_3}{t_3} + \dots + \frac{T_n}{t_n} \right) \times 100$$

$$\text{TWA} = 16.61 \log(D) + 90$$

Where exposures cannot be reduced by engineering controls, hearing protection is required to reduce exposures below 100% dose for those employees who have not suffered an occupational hearing loss, or a standard threshold shift (STS). Calculation of the STS is discussed in Section 2.5. For those employees who have suffered an STS, hearing protection must be worn when the exposure dose reaches 50% or 85 dB TWA.

Countries other than the United States use an exchange rate of 3 dB/doubling, which is the equivalent average level (L_{eq}). This is defined in Chapter 127. Dose is calculated as above using 3 for the exchange rate in place of 5. Table 2 illustrates the difference between doses calculated on the basis of a 3-dB and a 5-dB exchange rate for all sound equal to or greater than 80 dB A-weighted sound pressure level for an 8-h exposure.

2 COMPONENTS OF THE HEARING CONSERVATION PROGRAM

The key individual, discussed in a later section, is responsible for the implementation of the HCP elements including:

- Initial site noise exposure survey
- Audiometric testing and assessment
- Notification of worker and employer
- Training and education
- Recordkeeping
- Noise control program
- Hearing conservation program evaluation

2.1 Site Noise Survey

A site noise survey is needed to determine whether a hearing conservation program is required at a particular facility. If such a survey reveals exposures above the criterion level, then the next step is to conduct individual dosimetry on a representative sample of employees. This sample should include all job functions that are potentially exposed above the selected criterion noise level. The results of the dosimeter will demonstrate several things: those employees who must be included in hearing conservation program, those areas and processes that contribute to the overexposure, and the tasks that are carried out by employees that cause the overexposures. For a hearing conservation program to be effective it is important to understand how an employee's dose accumulates to identify those tasks that could be subject to engineering controls.

2.1.1 Initial Walk-through The most important purpose of the initial walk-through is to gain an understanding of the facility and the work processes that are carried out. These will strongly influence the sound exposures of employees who are assigned to different job functions. This should include discussions with both management and employee representatives. Frequently, the employee representatives will offer different explanations of job functions than will management. After gaining an understanding of job functions and the layout of the facility, a sound survey comprising measurements of A-weighted sound pressure levels may be started.

Ideally, each job function in each area of the facility should be delineated, tabulated, and a short sample of the sound pressure level at each position should be measured. Based on the job functions and facility layout, the surveyor should determine the maximum sound levels to which employees are exposed and also a representative estimate of the TWA exposures. If the walk-through survey reveals few measured sound pressure levels above the [85 dB A-weighted sound pressure level] criterion and no estimated time weighted averages above the action level, there is no need for a hearing conservation program. Measured sound pressure levels should be documented and a summary prepared showing the monitoring locations and the results for future documentation of potential employee exposures.

In some cases the selected criterion above which the employee should not be exposed may be selected by management to be lower than a governmentally mandated level. In that case the company criterion is substituted for the regulatory limit.

Table 2 Comparison of Dose for an 8-h Exposure at Level, L , for a 3 and a 5-dB Exchange Rate Including All Contributions to Exposure at or Above 80 dB

A-weighted Sound Pressure Level (dB)	5-dB Exchange Dose	3-dB Exchange Dose
80	0.25	0.10
85	0.50	0.31
90	1.00	1.00
95	2.00	3.17
100	4.00	10.08
105	8.00	32.00
110	16.00	101.59
115	32.00	322.54

2.1.2 Individual Dosimetry Noise dosimeters integrate the instantaneous sound exposures to which the worker is subjected over the duration of the measurement—a full or a partial shift. These instruments are capable of employing selected exchange rates depending on the jurisdiction for which the exposure is evaluated. Dosimetry will reveal typical work shift exposures for each job function. Although many audio dosimeters exist that will monitor and calculate a single dose, these instruments are of limited benefit since they serve only to identify the overall level at which the individual is exposed. Using simple dosimeters can provide only an estimate of the number of people to be included in hearing conservation programs. Further, some instruments will produce a single value corresponding to the dose accumulated during the measurement period while others will produce a time history that depicts the moment-by-moment accumulation of the dose.

Single Dose Exposure measurements that produce a single-number dose are useful to demonstrate compliance with regulations. In the event that measurements reveal an employee overexposure, these results cannot provide information that supports further efforts to mitigate those overexposures. With the exception of a task in which the employee is subjected to a source of constant noise emission, there is no means to identify the process responsible for the majority of the accumulated dose without a time history of the exposure.

Time History Using time history dosimeters provides substantially more useful information. In addition to demonstrating the worker exposure, if the individual is instructed to keep a log of job tasks during the

monitoring, or if the surveyor keeps such a record, comparison of the log with the dosimeter time history can reveal those tasks that are responsible for the majority of the workers exposure. This is useful in planning either an engineering noise control or administrative program to reduce exposure.

As an example, Fig. 1 shows an employee exposure throughout a work shift. From noon to 1 p.m. exposures are low during the lunch break. Using a chipping hammer on a truck muffler from 9:30 a.m. to 10 a.m. produces the highest exposures during the shift. An impact wrench produces an increased exposure in the afternoon. Overall, the chipping hammer alone comprises 56% of this daily exposure of 128% (by the OSHA 5-dB exchange). Modifying this single task (e.g., by using a cutting torch instead of a chipping hammer) could reduce the exposure to 72% or a TWA of 88 dB from 92 dB.

Octave-Band Measurements for Noise Control

Effective noise control engineering requires detailed understanding of the mechanism of noise production of each contributing source as well as a detailed characterization of the spectrum and level of the contributions. Although the details of measurements for noise control are beyond the scope of this chapter, several American and international standards provide guidance for these measurements. Among these, International Organization for Standardization (ISO) 3746:1995⁶ can provide data for both noise remediation and for prediction of noise levels that will be produced when equipment is placed into a facility. Similarly, American National Standards Institute (ANSI) S12.16–1992⁷ is useful in this context.

Figure 1 Single-shift exposure time history.

Following identification of the processes that contribute to the exceedance of the criterion noise dose, octave-band measurements should be taken to provide the basis on which to implement noise mitigation. Sound pressure levels must be sampled over the entire equipment duty cycle to define those components of the process that are responsible for the major contribution. This will enable the noise control engineer to develop optimal methods for reduction.

2.2 Employee Assessment and Testing

Evaluation of audiologic health in the industrial environment presents challenges different from the traditional diagnostic/rehabilitation setting. Not infrequently, audiometric evaluation is conducted to determine hearing handicap for the purposes of financial compensation of occupational hearing loss. In this adversarial situation the employee has an incentive to maximize the apparent impairment, while the employer is similarly motivated to demonstrate minimal impairment or nonoccupational causality. Accurate evaluation of employee hearing requires care by the audiometric technician to assure accurate results.

A critical aspect of any hearing conservation program is the baseline audiogram. At a minimum it serves as the benchmark against which future audiograms are compared. More importantly, the baseline audiogram establishes the hearing level of the employee at the start of his or her occupational noise exposure for the new employer. Some state compensation laws are structured such that the last employer of record is responsible for the full compensation burden for a hearing impairment unless the prior employer and the employee have been notified of a preexisting hearing impairment within a short period following new employment. Unless this notification is undertaken with the preemployment audiogram as its basis, a company with an effective hearing conservation program can find itself liable for a previous employer's ineffective program.

2.2.1 Audiometric Test Procedures Basic audiometric evaluations have been described in Chapter 120 of the *Encyclopedia of Acoustics*⁸ to which the reader is referred. Initial screening of the employee is conducted with a pure-tone audiogram including the audiometric test frequencies of 500, 1000, 2000, 3000, 4000, and 6000 Hz. Industrial audiometry differs from diagnostic audiometry in several aspects. First, the individual being tested may not be cooperative. In instances where there is labor unrest or where there is incentive for financial gain through one of several injury compensation programs, the results of testing may be biased. Second, the technician must be vigilant that the worker being tested has not been exposed to levels of noise prior to the evaluation that could elevate the hearing threshold and produce an artifactual threshold elevation.

Certification of the Technician Technicians who conduct the audiometric screening of employees must be trained to recognize certain pathological conditions

such as an ear canal occluded by wax or a perforated eardrum. They must also recognize an employee who has difficulty performing an audiogram for whatever reason. In United States, audiometric technicians may be certified through the Council for Accreditation in Occupational Hearing Conservation (CAOHC). This organization conducts training courses for instructors who then conduct classes to train the audiometric technicians.

For a discussion of basic audiometry refer to Chapter 120 in the *Encyclopedia of Acoustics*.⁸

2.2.2 Additional Audiometric Evaluation The tests described below are carried out by licensed audiologists. They are beyond the purview of the audiometric technician.

Pseudohypacusis To evaluate cases of pseudohypacusis, or malingering, special audiometric tests are available. Several of these do not rely on cooperation of the patient while others exploit the compromised perception of sound if one ear is substantially less sensitive than the other.

Perhaps the most telling indication of malingering is inconsistency of thresholds produced on successive test-retest audiograms. The judgment required to maintain a sound at a constant suprathreshold level is much more difficult than the judgment of whether a sound is heard. One method of maintaining sound at a constant level is to ignore the sound entirely and simply depress and release the switch indicating "heard" and "not heard" with a regular rhythm. This produces a small range tracing on an automated tracking audiogram. Another technique is for the listener to set the criterion for "heard" versus "not heard" relatively high and low, respectively, resulting in large, atypical, threshold variations.

Comparison of Speech Reception Threshold (SRT) and Pure-Tone Thresholds Since the majority of information in speech is carried in the frequencies between 500 and 2000 Hz, it is reasonable to expect the speech reception threshold (SRT) to closely approximate the pure tone average (PTA) of 500, 1000, and 2000 Hz. A large difference between the SRT and the PTA in a listener is suggestive of non-organic hearing impairment. Extensive experience⁹ with patients with confirmed pseudohypacusis showed that 70% exhibited SRTs at least 12 dB lower than the PTA. This discrepancy is one indication of malingering.

Delayed Auditory Feedback All speakers rely on feedback to modulate the level of their voice. This feedback is evidenced by the automatic increase or decrease of vocal effort depending on the level of background noise in which they speak. If a masking noise is applied as a listener reads aloud, the person's voice level will increase. This is known as the Lombard effect.

Although the Lombard effect itself can be used as a test for pseudohypacusis, a more dramatic

demonstration may be produced by presenting the listener's own speech as the masking sound. In a normal hearing individual auditory feedback is always present. Delaying the feedback, by presentation through a suitable electronic device, disrupts the normal processing of speech by the listener. The individual exhibits a change in speech rate and potentially vocal level. A normal hearing listener will take longer to read the same passage with 200-ms delayed feedback than with undelayed feedback.

The test is conducted by presenting the delayed speech initially at 0 dB HL (normal hearing threshold) subsequently raising it in 10-dB increments. The hearing-impaired individual will be unaffected until the delayed speech exceeds the true hearing threshold while the normal hearing individual will be affected at lower levels.

2.3 Employee and Management Feedback (Key Individual)

To maintain commitment to the goals of the HCP periodic review of program effectiveness and individual employee hearing status is crucial. For the program to be effective a key individual should be designated to whom the employee can direct questions about any aspect of the program, especially the use of hearing protective devices (HPDs) and the results of annual audiometric evaluations. The key individual should be educated in the details of hearing conservation to the extent of being able to accurately answer those questions. This person should occupy a place in the sociology of the company that engenders the respect of both labor and management. The key individual should also be in the position of addressing questions about the program from management including operational details, program effectiveness, and costs. Motivation and support is the key to continued HCP efficacy.

2.3.1 Notification Almost without exception, an employee will ask, "How did I do?" at the completion of the audiogram. While it is not the responsibility of the audiometric technician to provide feedback, with the advent of computerized audiometry and databases, feedback can be provided at that point that there is or is not a change from the previous test.

If changes are noted, it is appropriate to schedule a retest at a later date. The employee can be advised of the need to retest and that a written notification of the audiometric results will follow. This will also provide the supervising medical personnel an opportunity to determine if an otologic referral is appropriate.

In addition to providing individual employees notification of the results of their test, it is advisable

to provide management with annual summaries of the program results. By reporting the data shown in Table 3, any problem area in a facility can be identified by comparing the number of standard threshold shifts found with those in other departments. Furthermore, examination of the number of individuals exhibiting improved thresholds and those exhibiting worse thresholds in any year is an indication of the reliability of the testing procedures.

2.3.2 Medical Referral Referral to an otologist for a complete otologic workup is recommended for any employee who exhibits hearing loss on the baseline examination. Especially in the case where a worker has either never had a hearing test or where that evaluation was several years earlier, a medical exam frequently reveals underlying auditory pathology unrelated to noise exposures that could result in serious health consequences. Furthermore, such an evaluation may obviate claims for compensation at a later date. If an otologic examination is warranted, the physician will communicate the results of the exam to the employee.

2.4 Training and Education

Proper use and fitting of hearing protectors and the effects of noise on hearing are two topics that should be included in the employee education phase of the HCP. In companies that hold regular safety meetings this is most efficiently accomplished during one of those safety meetings. Material that can be used for the education and training is available from several sources, including the manufacturers of HPDs, professional industrial hygiene organizations, and the federal government. An excellent source of information on specific educational and training strategies is *The Noise Manual*.¹⁰

2.5 Recordkeeping

Maximum benefit to the employee and the employer occurs when full records of the HCP are maintained. OSHA requires only that after comparison of the current audiogram with the baseline audiogram, if an STS of 10 dB or more (average change at 2000, 3000, and 4000 Hz) has occurred, it must be recorded on the OSHA recordkeeping forms provided that, in addition, the average hearing threshold at those frequencies in the same ear is 25 dB or greater. All thresholds are referred to audiometric zero. If a threshold shift is determined to be nonoccupationally related, it need not be reported on the OSHA form. An excellent summary of recordkeeping rules may be found on the CAOHC website at www.caohc.org/oshafinal.html.

Table 3 Sample Database to Report Annual Summaries to Management

Department	Number Employees Screened	Number STS Identified	Number Cases Worse by 10 dB	Number Cases Better by 10 dB	Number Referred to Otologist	Number STS Classified Occupational	Average Department Exposure Dose

This said, it is important that the employer document both the threshold shift and the determination of nonoccupational causation in the event of future tort claims. Additionally, HCP records should include noise surveys and should document mitigation that was carried out as part of the company effort to reduce employee noise exposure. This information forms the basis for the defense of any litigation related to hearing loss within the company.

2.6 Exposure Reduction

2.6.1 Personal Protection Hearing protection devices are covered in Chapter 31 to which the reader is referred.

2.6.2 Engineering Controls Reduction of source noise levels is the preferred method of employee exposure protection. The sound survey carried out in the facility can serve as the basis for source level reduction if it has included both time history dosimetry and one-third octave-band sound pressure level measurements. With these data the offending equipment or process responsible for the employee overexposures can be identified and appropriate engineering measures may be implemented. The detailed protocol for a noise control program is beyond the scope of this chapter and may be found in other sections of this handbook.

2.6.3 Administrative Controls Where engineering controls are not feasible, the remaining choice is to administratively limit employee noise exposure duration. This can be accomplished by rotating employees in and out of the high noise exposure areas throughout the work shift, taking care to limit the overall dose to the permissible exposure level. As this may have

implications for production goals, it is often the least desirable of options.

3 EVALUATION OF THE HEARING CONSERVATION PROGRAM

3.1 Statistical Review of the Company Database

On a facilitywide basis, occupational NIHL may be considered a public health issue and treated as such. The effectiveness of the intervention strategy, the hearing conservation program, can be evaluated in the same manner as any other public health program. Comparison of pre- and postintervention rates of “disease” within the facility and with expected rates of the “disease” with normative dose–response data are typical metrics appropriate for this evaluation. In this case, the dose–response relationship for development of NIHL is known from the ISO 1999¹¹ databases. Evaluation of the HCP is a statistical exercise similar to studying the epidemiology of the disease.^{12,13}

Procedures for the calculation of expected NIHL can be found in ANSI S3.44–1996,¹⁴ Section 6.3, to which the reader is referred for detailed information. Predicted values over a limited number of exposures are shown in Fig. 2.

Two different aspects of a hearing conservation program should be evaluated: quality and effectiveness. The *effectiveness* of a program is judged by the rate of new cases of occupational NIHL that develop. This rate may be biased by program errors that increase or decrease the rate from one test cycle to the next. The quality of the program relates to the consistency of test results and to the other factors such as training

Figure 2 ISO 1999 30-year-old male hearing thresholds.

and feedback that affect the compliance of employees with the requirements of the HCP.

A preliminary gauge of program effectiveness may be determined from annual summaries of HCP monitoring results. Rates of NIHL lower than those predicted from the ANSI/ISO dose-response predictions are suggestive of an effective program if the data are reliable. Indicators of data quality are small variations between years using a metric of the percent of individual thresholds better or worse or the percent worse in sequential years of testing. Details of the technique of comparison can be found in the AIHA *Noise Manual*.⁹ Although there is some controversy of the validity of details of the use of database comparisons, the overall concept can provide useful insights into the quality of an HCP.

3.2 Comparison with Normative Data (ISO 1999/ANSI S3.44)

Additionally, hearing threshold level data for groups in an HCP may be compared with the referenced databases in ISO 1999¹¹/ANSI S3.44.¹⁴ A higher threshold for a particular age cohort with a known exposure in comparison to the referenced databases suggests reason for review of the HCP effectiveness. Comparison of populations in different departments within the facility is also instructive.

An HCP with effective hearing protection should exhibit similar trends of hearing threshold changes across departments with different exposures because the HPDs should reduce all exposures to below the PEL. The department exhibiting higher mean threshold shifts than others should be reviewed for adequacy of the HCP implementation.

4 EVALUATING CAUSALITY

4.1 Patterns of Noise-Induced Hearing Loss

Sounds of different frequency are distributed spatially within the cochlea. The classical pattern of noise-induced hearing loss begins with a decrease of thresholds in the frequencies corresponding to that place in the cochlea at which 4 kHz sounds are localized. As the hearing impairment progresses, the "4 kHz notch" deepens and extends to higher and lower frequencies. Typical progressions of NIHL, based on the ISO 1999¹¹ male database, are shown in Figs. 2 and 3.

For a typical 30-year-old male exposed to 85 dB over his working life, there is a small threshold deficit at 4 kHz. A cohort of the same age but exposed to 95 dB TWA for the same duration exhibits a pronounced threshold deficit at 4 kHz and the adjacent frequencies. The individual exposed at 100 dB TWA for that same period exhibits the pronounced hearing loss shown in Fig. 2.

That exposure level is more important than duration is seen by comparison with Fig. 3.

This shows population thresholds for males aged 30 to 60 years exposed at 90 dB TWA over their working lives. The difference between the 30-year-old cohort and the 60-year-old cohort is only about 5 dB at the most affected frequency of 4 kHz.

4.2 Comparison of Individual NIHL with Population Databases

Although it is not possible to predict an individual's NIHL based on level and duration of exposure, comparison of an employee's threshold with the population can be instructive. Figure 4 illustrates a

Figure 3 ISO 1999 90-dB exposure male hearing thresholds by age.

Figure 4 Female claimant 1975 audiograms.

range of hearing thresholds for female population exposed to 90 dB TWA for 13 years and for an individual similarly exposed. Predicted 90th and 10th percentile thresholds are shown. An individual exhibiting poorer thresholds than expected for the most sensitive subgroup is either exposed at levels higher than 90 dB TWA or may have hearing impairment of nonoccupational origin.

In this case, for a 13-year exposure at 90 dB, the hearing thresholds for a person claiming occupational NIHL at all frequencies other than 2 kHz are poorer than the predicted thresholds for the 10th percentile of the population. Furthermore, the pattern of hearing loss is atypical of NIHL; there is a low-frequency component and a substantial impairment at high frequencies. Twenty-two years after the first audiogram (Fig. 5) the new hearing profile for this person exhibits similar impairments at 4 and 6 kHz with a worsening of thresholds of as much as 40 dB in the lower frequencies. This is clear evidence of nonoccupational etiology of the impairment.

The audiometric profile in 1975 should have been cause for an otologic referral because of the departure from the normative thresholds.

4.3 Retrospective Exposure Assessment Based On Current Hearing Levels

Given these possibilities, a retrospective noise survey database is invaluable. The combination of hearing impairments inconsistent with dose-response functions in the ISO/ANSI standards in support of previous exposure levels from past noise surveys is powerful evidence that the hearing impairment was not the result of occupational noise exposure.

4.4 Role of the Otologist

At this point, referral to an otologist for a complete otologic examination is indicated. The otologist should be experienced in the evaluation of occupational hearing loss. A battery of tests included in this examination can definitively determine the cause of the threshold deficit.

Figure 5 Female claimant 1997 audiograms.

4.5 Nonoccupational Causes of Hearing Loss

Recent evidence in animal models as well as some epidemiologic studies has suggested that certain industrial chemicals may potentiate the effect of noise exposure by producing oxidative stress in the cochlea.^{15,16} These substances include, among others, acrylonitrile, organic solvents, aminoglycoside antibiotics, and others. For this reason, it is recommended that the employee occupational history include summaries of chemical exposures as well as noise exposure.

CHAPTER 34

RATING MEASURES, DESCRIPTORS, CRITERIA, AND PROCEDURES FOR DETERMINING HUMAN RESPONSE TO NOISE

Malcolm J. Crocker

Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

People are exposed to noise during daytime and nighttime hours. During the day the noise can interfere with various activities and cause annoyance, and at night it can affect sleep. Very intense noise can even lead to hearing damage (see Chapters 19, 20, 27 to 29, and 33). In the daytime the activities most affected are communications that involve speech between individuals, speech in telephone communications, and speech and music on radio and television. If the noise is more intense, it is normally more annoying, although there are a number of other attitudinal and environmental factors that also affect annoyance. There are many different ways to measure and evaluate noise, each normally resulting in a different noise measure, descriptor, or scale. The various measures and descriptors mainly result from the different sources (aircraft, traffic, construction, industry, etc.) and the different researchers involved in producing them. From these measures and descriptors, criteria have been developed to decide on the acceptability of the noise levels for different activities. These criteria are useful in determining whether noise control efforts are warranted to improve speech communication, reduce annoyance, and lessen sleep interference. This chapter contains a review and discussion of some of the most important noise measures and descriptors. In the past 20 to 30 years these measures and descriptors have undergone some evolution and change as researchers have attempted to find descriptors that best relate to different human responses and are more easily measurable with improved instrumentation. For completeness this evolution is traced and some measures and descriptors are described that are no longer in use, since knowledge of them is needed in the study of the results of various noise studies reported in the literature.

2 LOUDNESS AND ANNOYANCE

As the level of the noise is increased, it is accompanied by an apparent increase in loudness. Loudness may be considered to be the subjective evaluation of the intensity of a noise when this evaluation is divorced from all the attitudinal, environmental, and emotional factors that may affect the listener's assessment of the annoying properties of the noise. Chapter 21

contains a detailed discussion on the loudness of noise. Generally, if a noise is louder, it is judged to be more annoying and vice versa, although there are exceptions. Table 1 shows some of the acoustical and nonacoustical factors that can contribute to the annoyance caused by noise. Some of the factors shown in Table 1 are also important in considerations of the effects of noise on speech communication (see Sections 6 and 7) and on sleep (see Section 15.1 and Chapter 24). The annoyance caused by noise is discussed further in Section 15.2 and in detail in Chapter 25.

3 LOUDNESS AND LOUDNESS LEVEL

As discussed in Chapter 21, which contains an in-depth description of the loudness of sound, and Chapter 67, the human ear does not have a uniform sensitivity to sound as its frequency is varied. Figure 2 in Chapter 21 and Fig. 2 in Chapter 67 show equal-loudness-level contours. These contours connect together pure-tone sounds that appear equally loud to the average listener. Recently, slightly modified contours have been proposed by Moore and co-workers.¹⁻³ See Fig. 1. In 2005, a new American National Standards Institute (ANSI) standard (ANSI S3.4-2005)⁴ for the calculation of the loudness of steady sounds was published. This 2005 ANSI standard⁴ is based on the loudness model of Moore et al.¹ The model in ANSI S3.4-2005 gives reasonably accurate predictions of a wide range of data on loudness perception.¹ However, the equal-loudness contours predicted by the model shown as the dotted

Table 1 Some Acoustical and Nonacoustical Factors That Contribute to Annoyance Caused by Noise

Acoustical Factors	Nonacoustical Factors
Sound pressure level	Time of day
Frequency spectrum	Time of year
Duration	Necessity for noise
Pure-tone content	Community attitudes
Impulsive character	Past experience
Fluctuation in level	Economic dependence on source

Figure 1 The bottom curves (marked Hearing Threshold) show the absolute thresholds (free field, frontal incidence, binaural listening) predicted by the original (1997) model¹ (dotted line), the modified model (dashed line), and as published in ISO 389-7 (2005),⁷ (solid line). The other curves show equal-loudness contours as predicted by the original model, the modified model, and as published in ISO 226 (2003)⁸ (dotted, dashed, and solid lines, respectively).

lines in Fig. 1 differ substantially from those in the International Organization for Standardization (ISO) standard that was applicable at the time (ISO 226, 1987),⁵ which in turn were based on the 1956 data of Robinson and Dadson.⁶

Similar contours have been determined experimentally for bands of noise instead of pure tones. The unit of (linear) loudness is the *sone*. A sone is defined as the loudness of a pure tone, which has a sound pressure level of 40 dB at 1000 Hz. A sound that is twice as loud is said to have a loudness of 2 sones and so on. The loudness level of a 1000-Hz pure tone of 40 dB is defined as 40 *phons*. If the 1000-Hz pure tone is raised in level by 10 dB, it appears to be about twice as loud to the average listener. Thus a doubling of the loudness has been defined to be equivalent to an increase in loudness level of 10 phons. The relationship between loudness S and loudness level P (for both pure tones and bands of noise) is thus given by Eq. (1) and shown in Fig. 2:

$$S = 2^{(P-40)/10} \quad (1)$$

The preceding discussion has concerned the loudness of pure tones. Equal loudness contours for bands of noise were determined experimentally and independently by Stevens and Zwicker and standardized.⁹⁻¹² These can be used to evaluate the loudness (in sones) of noise sources. The procedure used in the Stevens mark VI method is to plot the noise spectrum in either octave or one-third-octave bands onto the loudness index contours. The loudness index (in sones) is determined for each octave (or one-third-octave) band and the total loudness S is then given by

$$S = S_{\max} + 0.3 \left(\sum S - S_{\max} \right) \quad (2)$$

Figure 2 Relationship between the loudness (in sones) and the loudness level (in phons) of a sound.

where S_{\max} is the maximum loudness index and $\sum S$ is the sum of all the loudness indices. The 0.3 constant (used for octave bands) in Eq. (2) is replaced by 0.15 for one-third-octave bands. The Stevens method assumes that the sound field is diffuse and does not contain any prominent pure tones. The Zwicker method is based on the critical band concept and, although more complicated than the Stevens method,

can be used either with diffuse or frontal sound fields. Complete details of the procedures are given in the ISO standard,¹² and Kryter¹³ has discussed the critical band concept in his book. See also the updated ANSI standard, ANSI S3.4-2005.⁴ This is based on the Zwicker method^{10,11} but uses the more recent data of Glasberg and Moore.^{1,3} In recent years the Zwicker method^{10,11} has become more widely used than the Steven's method because it appears to relate better to the physiological response of the human auditory system.

4 NOISINESS AND PERCEIVED NOISE LEVEL

4.1 Noisiness

Although the level of noise or its loudness is very important in determining the annoyance caused by noise, there are other acoustical and nonacoustical factors that are also important. In laboratory studies, people were asked to rate sounds of equal duration in terms of their noisiness, annoyance, or unacceptability.^{16,17} Using octave bands of noise, Kryter and others have produced *equal noisiness index* contours. These equal

noisiness contours are similar to those for equal loudness, except that at high frequency less sound energy is needed to produce equal noisiness and at low frequency more is needed. The unit of noisiness index is the *noy* N . Equal noisiness index curves are shown in Fig. 3. The procedure to determine the logarithmic measure, the *perceived noise level* (PNL), is quite complicated and has been standardized.¹⁸ It has also been described in several books.¹⁹⁻²¹ (See also Chapter 43.) Briefly, it may be stated as follows. Tabulate the octave band (or one-third-octave band) sound pressure levels of the noise. Calculate the noisiness index in noys for each band in Fig. 3.

Then calculate the total noisiness index N , from

$$N_t = N_{\max} + 0.3 \left(\sum N - N_{\max} \right) \quad (3)$$

where N_{\max} is the maximum noisiness index and $\sum N$ is the sum of all the noisiness indices. If one-third-octave bands are used, the constant 0.3 for octave bands in Eq. (3) is replaced by 0.15.

Figure 3 Contours of perceived noisiness.

The total perceived noisiness index N_t (summed over all frequency bands) is converted to the PNL or L_{PN} from

$$L_{PN} = 40 + (33.22) \log N_t \quad (4)$$

The procedure is similar to that for calculating loudness level (phons) from loudness (sones). Some have questioned the usefulness of this procedure since listeners in laboratory experiments do not seem to be able to distinguish between (1) loudness and (2) noisiness and (3) annoyance. Despite this, the procedure has been widely used in assessing single-event aircraft noise. In the United States the Federal Aviation Administration (FAA) has adopted the effective perceived noise level for the certification of new aircraft. As an example, the noisiness of the spectra given in Fig. 6 of Chapter 119 can be calculated. The takeoff noise shown by the upper dashed line of Fig. 6 of Chapter 119 has a noisiness of 170 noys and a perceived noise level of 114 PNdB. Perceived noise level has received wide acceptance in many countries as a measure of aircraft noisiness with and without tone corrections.

4.2 Effective Perceived Noise Level

Although PNL can be used to monitor the peak noise level of an aircraft passby (or flyover or flyby), this measure does not take into account the variation of the noise or its duration. Experiments have shown that annoyance and noisiness increase both with the magnitude and with the duration of a noise event. Noise that is of long duration is normally judged to be more annoying than noise of short duration. Figure 4 shows a PNL time history of a flyover of a typical fanjet aircraft. As the airplane approaches, the discrete

Figure 4 Typical noise history of a fanjet aircraft flyover.¹²

frequency whine caused by fan and compressor noise radiated from the engine inlets is very evident. When the airplane is overhead, the noise is dominated by that from the fan exit and is again mostly whine. When the plane has passed, the low-frequency jet rumble is heard. The peaks for each source occur at different times since each source is very directional. The inlet noise is mainly “beamed” forward in the flight direction, while the jet noise is mainly radiated backward about 45° to the jet exhaust direction.

In addition to the effects of noise level and duration, the effects of tonal content must be considered. If the noise contains pure tones along with the broadband noise spectrum, it is also judged to be noisier than without such tones. To account for these effects the effective perceived noise level (EPNL) or L_{EPN} has been defined as

$$L_{EPN} = L_{PN,max} + C + D \quad (5a)$$

where C is the correction factor for pure tones (between 0 and 6 dB, depending on frequency and the tone magnitude in relation to the broadband noise in adjacent frequency bands) and D is a correction for duration.¹⁷⁻¹⁹ EPNL is simply a time integration of the tone-corrected perceived noise level. Equation (5a) does not directly reveal the time integration. However, EPNL is defined in Federal Aviation Regulations (FAR) Part 36, and also International Civil Aviation Organization (ICAO) Annex 16 as

$$L_{EPN} = 10 \log \{ \text{sum} [10^{L_{PN}(k)/10} \Delta t] \} - 10 \quad (5b)$$

where $L_{PN}(k)$ is the perceived noise level plus the tone correction of the k th sample in the time history. There are some complexities regarding the maximum value of $L_{PN}(k)$ also known as $PNLT(k)$ if the tone correction at that moment is not as large as the average tone correction for the two preceding and two succeeding samples in which case this average replaces the tone correction value for sample k . But essentially Eq. (5b) states the summation process that is actually taking place, just as in any time-integrated measure of noise level.

The EPNL takes into account tonal content, duration, and the level of the noise by integrating the tone-corrected PNL over the duration of the event. An example of how the tone-corrected PNL varies with an aircraft flyover is shown in Fig. 5. For aircraft certification purposes h is equal to 10 PNdB, Δt is equal to 0.5 s, and the duration, d , is determined by the 10-dB down points shown as A and B in Fig. 5.

The procedure for calculating L_{EPN} is quite complicated, and its description is beyond the scope of this chapter. It is fully described in standards^{16,21,22} and in some other books.¹⁷⁻¹⁹ There is a useful, approximate relationship between A-weighted sound pressure level, $L(A)$ and PNL. For aircraft noise spectra this is generally taken to be $PNL = L(A) + 13$, and $EPNL = SEL + 3$ (SEL is sound exposure level). The A-weighting filter and A-weighted sound pressure level are discussed in the next section.

Figure 5 How tone-corrected perceived noise level may vary in an aircraft flyover, showing some of the labeling used in the calculation of effective perceived noise level.²⁰

5 WEIGHTED SOUND PRESSURE LEVELS

Figure 1 in this chapter and Fig. 2 in Chapter 21 show that the ear is most sensitive to sounds in the mid-frequency range around 1000 to 4000 Hz. It has a particularly poor response to sound at low frequency. It became apparent to scientists in the 1930s that electrical filters could be designed and constructed with a frequency response approximately equal to the inverse of these equal loudness curves. Thus A-, B-, and C-weighting filters were constructed to approximate the inverse of the 40-, 70-, and 90-phon contours (i.e., for low-level, moderate, and intense sounds), respectively. (See Fig. 1.) In principle, then, these filters, if placed between the microphone and the meter display of an instrument such as a sound level meter, should give some indication of the loudness of a sound (but for pure tones only).

The levels measured with the use of the filters shown in Fig. 6 are commonly called the A-, B-, and C-weighted sound levels. The terminology A-, B-, and C-weighted sound pressure levels is preferred by ISO to reduce any confusion with sound power level and will be used wherever possible

Figure 6 A-, B-, and C-weighting filter characteristics used with sound level meters.

throughout this handbook. The A-weighting filter has been much more widely used than either the B- or C-weighting filter, and the A-weighted sound pressure level measured with it is still simply termed by ANSI as the sound level or noise level (unless the use of some other filter is specified). Because it is simple, giving a single number, and it can be measured with a low-cost sound level meter, the A-weighted sound pressure level has been used widely to give an estimate of the loudness of noise sources such as vehicles, even though these produce moderate to intense noise. Beranek and Ver have reviewed the use of the A-weighted sound pressure level as an approximate measure of loudness level.²³ The A-weighted sound pressure levels are often used to gain some approximate measure of the loudness levels of broadband sounds and even of the acceptability of the noise. Figure 7 shows that there is reasonable correlation

Figure 7 Relation between subjective response and A-weighted sound pressure level for diesel engine trucks undergoing an acceleration test; •, values measured in 1960, ○, values measured in 1968. (From C. H. G. Mills and D. W. Robinson, *The Subjective Rating of Motor Vehicle Noise*, *The Engineer*, June 30, 1961; Ref. 39; and T. Priede, *Origins of Automotive Vehicle Noise*, *J. Sound Vib.*, Vol. 15, No. 1, 1971, pp. 61–73.)

between the subjective response of people to vehicle noise and A-weighted sound pressure levels for vehicle noise. The A-weighted sound pressure level forms the basis of many other descriptors described later in this chapter and of the SEL, single-event noise exposure level (SNEL), equivalent continuous sound pressure level L_{Aeq} , day-night level (DNL) (L_{dn}), and day-evening-night level (DENL) discussed in Chapters 1 and 119. The A-weighted sound pressure level descriptor is also used as a limit for new vehicles (Chapter 119) and noise levels in buildings (see Chapter 97 in the *Encyclopedia of Acoustics*) in several countries. Although the A-weighting filter was originally intended for use with low-level sounds of about 40 dB, it is now commonly used to rate high-level noise such as in industry where A-weighted sound pressure levels may exceed 90 dB. At such high levels the A-weighted sound pressure level and the loudness level are normally in disagreement.

6 ARTICULATION INDEX AND SPEECH INTELLIGIBILITY INDEX

The articulation index (AI) is a measure of the intelligibility of speech in a continuous noise. The AI was first proposed by French and Steinberg²⁴ and was extended later by Beranek and Ver.²³ Speech has a dynamic range of about 30 dB in each one-third-octave band from 200 to 6000 Hz, and the long-term root-mean-square (rms) overall sound pressure level at the speaker's lips is about 65 dB. In speech, vowels and consonants are joined together to produce not only words but sounds that have a distinctive personal nature as well. The vowels usually have greater energy than consonants and give the speech its distinctive characteristics. This is because vowels have definite frequency spectra with superimposed short-duration peaks. The articulation index ranges from AI = 0 to 1.0 corresponding to 0 and 100% intelligibility, respectively. If the AI is less than about 0.3, speech communication is unsatisfactory (only about 30% of monosyllabic words understood); while if the AI is greater than about 0.6 or 0.7, speech communication is generally satisfactory (with more than 80% of monosyllabic words understood). Methods to calculate the AI are somewhat complicated and are given in American National Standard (ANSI S3.5–1969)²⁵ and explained in several books.^{17,20} Since the calculation of AI is complicated, it will not be explained in detail here. The calculation of AI is also described briefly in Chapter 106. In 1997 the ANSI S3.5–1969 standard was updated and then further revised in 2002.²⁶ In this later standard, the AI has been renamed as the speech intelligibility index (SII). As before, the SII is calculated from acoustical measurements of speech and noise. The reader is referred to the new standard for the changes from AI to SII and complete details of the calculation of this index.²⁶ Because of the complication in the calculation of AI and SII, many favor the use of the speech interference level (SIL), which is easier to calculate. SIL is described in the next section of this chapter.

7 SPEECH INTERFERENCE LEVEL

The speech interference level is a measure used to evaluate the effect of background noise on speech communication.²³ The speech interference level is the arithmetic average of the sound pressure levels of the interfering background noise in the four octave bands with center frequencies of 500, 1000, 2000, and 4000 Hz [see ANSI S3.14–1977(R-1986)]. If the SIL of the background noise is calculated, then this may be used in conjunction with Fig. 8 to predict the sort of speech required for satisfactory face-to-face communication with male voices (i.e., for at least 95% sentence intelligibility). As an example, if the SIL is 40 dB and the speakers are males, they should be able to communicate with normal voices at 8 m. If the SIL increases to 50, raised voices must be used at 8 m. For females the SIL should be decreased by 5 dB (or the x axis moved to the right by 5 dB.) The shaded area of Fig. 8 shows the range of speech levels that normally occur as people raise their voices to overcome the background noise. Speech interference level is also discussed in Chapter 106. Because it is simpler to measure than the SIL, the A-weighted sound pressure level is sometimes used as a measure of speech interference, but with somewhat less confidence. Webster has produced a comprehensive diagram (see Fig. 9) that summarizes speech levels required for communication (at various distances) with 97% intelligibility of sentences for both outdoor and indoor situations.²⁷ Figure 9 is similar to Fig. 8 but contains some additional information concerning voice levels in different situations. With noise levels above 50 dB, people tend to raise their voice levels as shown by the “expected line” (at the left) for nonvital communication and the “communicating line” (at the right) of the diagonal shaded area for essential communication.

8 INDOOR NOISE CRITERIA

The speech interference level is mainly used to evaluate the effect of noise on speech in situations outdoors

Figure 8 Talker-to-listener distances (m) for male speech communication to be just reliable. (Reprinted from American Standard ANSI S3.14–1977.)

Figure 9 Comprehensive diagram summarizing speech levels for communication (at various distances) for 97% intelligibility of sentences on first presentation to listeners for both outdoors (free field) and indoor situations.²⁷

or indoors where the environment is not too reverberant. The A-weighted sound pressure level can be used as a guide for the acceptability of noise in indoor situations, but it gives no indication about which part of the frequency spectrum is of concern. A number of families of noise-weighting curves have been devised to evaluate the acceptability of noise in indoor situations. These include *noise criterion (NC) curves*, *noise rating (NR) curves*, *room criterion (RC) curves*, and *balanced noise criterion (NCB) curves*. The curves have resulted from the need to either specify acceptable noise levels in buildings or determine the acceptability of noise in existing building spaces. A major concern has been to determine the acceptability of air-conditioning noise. Beranek and co-workers²⁸⁻³¹ has been a major contributor to the development of the NC and NCB noise criterion curves. Beranek and co-workers²⁸⁻³¹ and Blazier³² were mainly responsible for the development of the RC room criterion curves. NR curves were devised by Kosten and van Os³³ and are similar to the NC curves. They have been standardized and adopted by the ISO. These noise-weighting curves are now reviewed briefly.

8.1 Noise Criterion Curves

The NC curves (Fig. 10) were developed from the results of a series of interviews with people in offices,

public spaces, and industrial spaces.^{28,29} These results showed that the main concern was the interference of noise with speech communication and listening to music, radio, and television. In order to determine the NC rating of the noise under consideration, the octave-band sound pressure levels of the noise are measured, and these are then plotted on the family of NC curves (Fig. 10). The noise spectrum must not exceed the particular NC curve specified in any octave band in order for it to be assigned that particular NC rating.²³ NC curves are also discussed in Chapter 106.

8.2 Noise Rating Curves

The NR curves are similar to the NC curves (see Fig. 10). They were originally produced to develop a procedure to determine whether noise from factories heard in adjacent apartments and houses is acceptable.³³ The noise spectrum is measured and plotted on the family of NR curves (Fig. 11) in just the same way as with the NC curves. One difference from the NC curves, however, is the use of corrections for time of day, intermittency, audible pure tones, fraction of time the noise is heard, and type of neighborhood. These corrections are made to the final NR rating and not to the octave band levels used to determine the NR. It has been found that in the range of NR or NC

Figure 10 Noise criterion (NC) curves.

Figure 11 Noise rating (NR) curves.

of 20 to 50 there is little difference between the results obtained from the two approaches.

8.3 Room Criterion Curves

Noise Criterion curves are not defined in the low-frequency range (16- and 31.5-Hz octave bands) and are also generally regarded as allowing too much noise in the high-frequency region (at and above

2000 Hz). Blazier based his derivation of the RC curves on an extensive study conducted for the American Society of Heating, Refrigeration, and Air Conditioning Engineers (ASHRAE) by Goodfriend of generally acceptable background spectra in 68 unoccupied offices.³² The A-weighted sound pressure levels were mostly in the range of 40 to 50 dB. Blazier³² found that the curve that he obtained from

Figure 12 Room criterion (RC) curves.

the measured data had a slope of about -5 dB/octave, and he thus drew a family of straight lines with this slope (see Fig. 12). He also found that intense low-frequency noise with a level of 75 dB or more in region A is likely to cause mechanical vibrations in lightweight structures (including rattles), while noise in region B has a low probability to cause such vibration. The value of the RC curve is the arithmetic average of the levels at 500, 1000, and 2000 Hz. Since these curves were obtained from measurements made with air-conditioning noise, they are mostly useful in rating the noise of such systems. RC curves are also discussed in Chapter 106.

8.4 Balanced Noise Criterion Curves

In 1989, Beranek^{30,31} modified the NC curves to include the 16- and 31.5-Hz octave bands and changed the slope of the curves so that it is now -3.33 dB/octave between 500 and 8000 Hz. He also incorporated the A and B regions as specified by Blazier³² in the RC curves. The rating number of a *balanced noise criterion* NCB curve is the arithmetic average of the octave band levels with midfrequencies of 500, 1000, 2000, and 4000 Hz. The result is a set of rating curves that are useful to rate air-conditioning noise in buildings (see Fig. 13). As an example of its use, a background noise spectrum from air-conditioning is plotted (as the dashed curve) in Fig. 13. The NCB is calculated from the formula $NCB = \frac{1}{4}(44 + 42 + 37 + 33)$ dB. Thus this background noise spectrum can be assigned a rating of NCB 39 dB. Such a noise spectrum might be just acceptable in a general office, and barely acceptable in a bedroom and living room in a house, but not acceptable

Figure 13 Balanced noise criterion (NCB) curves.

at all in a church, concert hall, or theater. NCB curves are also described in Chapter 106.

9 EQUIVALENT CONTINUOUS SOUND PRESSURE LEVEL

For noise that fluctuates in level with time it is useful to define the *equivalent continuous sound pressure level* L_{Aeq} , which is the A-weighted sound pressure level averaged over a suitable period T . This average A-weighted sound pressure level is also sometimes known as the *average sound level* L_{AT} in ANSI documents, so that $L_{Aeq} = L_{AT}$. The equivalent sound pressure level is given by

$$L_{Aeq} = 10 \log \left(\frac{1}{T} \int_0^T p_A^2 dt / p_{ref}^2 \right) \text{ dB} \quad (6)$$

where p_A is the instantaneous sound pressure measured using an A-weighting frequency filter and p_{ref} is the reference sound pressure 20 μPa . The averaging time T can be specified as desired to range from seconds to minutes or hours.

The average sound pressure level (or the equivalent continuous sound pressure level L_{Aeq}) can be conveniently measured with an integrating sound level meter or some other similar device. Since it accounts both for magnitude and the duration, L_{Aeq} has become one of the most widely used measures for evaluating community (environmental) noise from road traffic, railways, and industry.³⁴⁻³⁶ L_{Aeq} has also been found to be well correlated with the psychological effects of noise.^{37,38} For community noise, a long-period T is usually used (often 24 h). In the literature L_{Aeq} is often abbreviated to L_{eq} .

10 DAY-NIGHT EQUIVALENT SOUND PRESSURE LEVEL

In the United States during the 1970s, the Environmental Protection Agency developed a measure, from the equivalent sound pressure level, known as the *day-night equivalent level* (DNL) or L_{dn} that accounts for the different response of people to noise during the night.³⁸

$$L_{dn} = 10 \log \frac{15(10^{L_d/10}) + 9(10^{(L_n+10)/10})}{24} \quad (7)$$

where L_d is the 15-h daytime A-weighted equivalent sound pressure level (from 07:00 to 22:00) and L_n is the 9-h nighttime equivalent sound pressure level (from 22:00 to 07:00). The nighttime noise level is subjected to a 10-dB penalty because noise at night is deemed to be much more disturbing than noise during the day. This 10-dB nighttime penalty is analogous to the 10-dB nighttime penalty applied in both the composite noise rating (CNR) and the noise exposure forecast (NEF), as described in Section 12. The day-night equivalent level has become increasingly used in the United States and some other countries to evaluate community noise and in particular airport noise.^{36,39} In 1980 the U.S. Federal Interagency Committee on Urban Noise (FICON) adopted L_{dn} as the appropriate descriptor of environmental noise in

residential situations.³⁶⁻⁴⁰ Its use is also discussed in Chapter 106, where it is termed day-night average sound pressure level.

11 PERCENTILE SOUND PRESSURE LEVELS

The equivalent sound pressure level discussed above accounts for the fluctuation in noise level of an unsteady noise by forming an average sound pressure level to find an equivalent steady A-weighted sound pressure level. There is, however, some evidence that unsteady noise (e.g., from noise sources such as passing road vehicles or aircraft movements) is more disturbing than steady noise. To try to better account for fluctuations in noise level and the intermittent character of some noises, *A-weighted percentile sound pressure levels* are used in some measures, in particular those for community and traffic noise.^{34,41,42} The level L_n is defined to represent the sound pressure level exceeded $n\%$ of the time, and thus L_{10} , for example, represents the sound pressure level exceeded 10% of the time.

Figure 14 gives an example of L_{10} , L_{50} , and L_{90} levels and a cumulative distribution. It is seen in this schematic example figure that the A-weighted level exceeded 10% of the time L_{10} is 85 dB, while L_{50} is sometimes termed the *median* noise level, since for half the time the fluctuating noise level is greater than L_{50} and for the other half it is less. L_{50} is used in Japan for road traffic noise. Levels such as L_1 or L_{10} are used to represent the more intense short-duration noise events. L_{10} is used in Australia and the United Kingdom (over an 18-h 06:00 to 24:00 period) as a target value for new roads and for insulation regulations for new roads. Levels such as L_{90} or L_{99} are often used to represent the minimum noise level, the residual level from a graphic level recorder, or the average minimum readings observed when reading a sound level meter. Figure 15 shows the outdoor A-weighted sound pressure levels recorded in 1971 at 18 locations in the United States. Values of L_{99} , L_{90} , L_{50} , L_{10} , and L_1 are shown for the period 07:00 to 19:00.^{34,39} The small range in levels in recordings 1 and 4 (urban situations) and the large range in levels in recordings 6, 11, 13, and 18 (situations involving aircraft overflights) are very evident. Obviously road traffic usually creates more steady noise, while aircraft movements lead to more extreme variations in noise levels. Percentile sound pressure levels are also discussed in Chapter 106.

12 EVALUATION OF AIRCRAFT NOISE

The noise levels around airports are of serious concern in many countries. Several attempts have been made to produce measures to predict and assess the annoyance caused by aircraft noise in the community. A study of rating measures in 1994 showed 11 different measures in use in the 16 countries studied.³⁶ The following measures merit brief discussion.

12.1 Composite Noise Rating

The CNR has a long history dating back to the early 1950s.⁴³⁻⁴⁵ Originally, the basic measure it used was the level rank—a set of curves placed

Figure 14 (a) Percentile levels and (b) cumulative probability distribution function of percentile levels.

Figure 15 A-weighted sound pressure levels measured in 1971 at 18 locations in the United States. Values of the percentile levels L_{99} , L_{90} , L_{50} , L_{10} , and L_1 , where L_n is A-weighted sound pressure level exceeded n percent of the time are shown for the period 0700–1900 h. (From Refs. 34, 35, and 39)

about 5 dB apart in the midfrequency range, rather similar to the NC and NR curves described earlier. The level rank was obtained by plotting the noise spectrum on the curves and finding the highest zone into which the spectrum protruded. The rank found initially plus the algebraic addition of corrections

gave the CNR. The corrections⁴³ were for spectrum character, peak factor, repetitive character, level of background noise, time of day, adjustment to exposure, and public relations. The value of CNR obtained was associated with a range of community annoyance categories found from case histories—ranging from no

annoyance, through mild annoyance, mild complaints, strong complaints, and threats of legal action, to vigorous community response.

In the late 1950s, the CNR was adapted to apply to the noise of military jet aircraft⁴⁶ and later of commercial aircraft.⁴⁷ The calculation was further modified later when applied to commercial aircraft by using the PNL instead of the level rank or the sound pressure level (SPL) just referred to. More details on the calculation of CNR are given in the *Handbook of Acoustics*, Chapter 64.

The final version of CNR does not contain any corrections for background noise, previous experience, public relations, or other factors such as the presence of pure tones. Although CNR is no longer used, it is discussed here for completeness and because it has formed the basis for some of the other noise measures and descriptors, such as NEF, which follow.

12.2 Noise Exposure Forecast

The NEF is a similar measure to CNR, but it uses the effective perceived noise level instead of PNL.^{48,49} Thus NEF automatically takes account of the annoying effects of pure tones and the duration of the flight events. The use of NEF has been superseded in the United States and most other countries by the day–night level L_{dn} or the day–evening–night level L_{den} .

12.3 Noise and Number Index

The *noise and number index* (NNI) is a subjective measure of aircraft noise annoyance first developed and used in the United Kingdom. The NNI was the outcome of surveys in 1961 and 1967 of noise in the residential districts within 10 miles of London (Heathrow) Airport.^{50,51} NNI is based on a summation of $\langle \text{PNL} \rangle_N$ terms weighted by aircraft movements. $\langle \text{PNL} \rangle_N$ is the average peak noise level of all aircraft operating during a day, and N is the number of aircraft movements. Here PNL is the peak perceived noise level produced by an individual aircraft during the day and N is the number of aircraft operations of that type over a 24-h period.

In 1988 NNI was superseded in the United Kingdom by a measure based on the A-weighted L_{eq} . The L_{eq} is determined over the period 07:00 to 23:00. Noise at night is evaluated in terms of the size of the 90 SEL footprint of individual aircraft movements, or, less commonly, using L_{eq} determined over the period 23:00 to 07:00.

12.4 Equivalent A-weighted Sound Pressure Level L_{eq} , Day–Night Level L_{dn} , and Day–Evening–Night Level L_{den}

In recent years some countries have continued to use NEF or NNI or similar noise measures or descriptors related to those that include a weighting based on the number of aircraft movements.³⁶ However, because they are much simpler to measure and seem to give adequate correlation with subjective response, there has been a move in several countries toward the

use of L_{eq} and L_{dn} .³⁶ In Germany, Luxembourg, and the United Kingdom L_{eq} has been adopted: (1) in Germany and Luxembourg with day (06:00 to 22:00) and night (22:00 to 06:00) periods, and (2) in the United Kingdom with an 18-h period only (07:00 to 23:00) (because nighttime flights are normally restricted). The European Union has specified the use of L_{den} to evaluate aircraft noise, which includes three periods: day, evening, and night, from which L_{den} is calculated. See Chapters 1, 114, and 119.

In the United States since publication of the Environmental Protection Agency's (EPA) *Levels document*³⁸ and other similar publications, the use of CNR and NEF has been superseded by the day–night equivalent level DNL (L_{dn}) for the assessment of the potential impacts of noise and for planning recommendations and land-use management near civilian and military airports.

13 EVALUATION OF TRAFFIC NOISE

13.1 Traffic Noise Index

In an attempt to develop acceptability criteria for traffic noise from roads in residential areas, Griffiths and Langdon⁵⁷ produced a unit for rating traffic noise, the *traffic noise index* (TNI). They measured A-weighted traffic noise at 14 sites in the London area and interviewed 1200 people at these sites in the process. Griffiths and Langdon excluded sites with noise sources other than traffic. They then used regression analysis to fit curves to the data. This indicated that L_{10} was better at predicting dissatisfaction than L_{50} or L_{90} , and that TNI was also superior to L_{10} , L_{50} , and L_{90} .

Use of the traffic noise index has not been widespread. The index attempts to make an allowance for the noise variability since fluctuating noise is commonly assumed to be more annoying than steady noise.

Some doubt has been cast on the conclusions of Griffiths and Langdon, and it has been suggested that the very short sample times (100 s in each hour) used may have resulted in underestimates of L_{10} and overestimates of L_{90} .⁵² TNI is not considered today to be significantly superior to either L_{10} or L_{eq} and has not been widely used.

Instead of TNI, the British government has adopted the A-weighted L_{10} , averaged over 18 h from 06:00 to 24:00, as the noise index to be used to implement planning and remedial measures to reduce the impact on people of road traffic noise.^{53–55} In addition the British government uses a 16-h L_{eq} and an 8-h L_{eq} for the case of land used for residential development.

13.2 Noise Pollution Level

In a later survey, Robinson⁵⁶ again concluded that, with fluctuating noise, L_{eq} , the equivalent continuous A-weighted sound pressure level on an energy basis, was an insufficient descriptor of the annoyance caused by fluctuating noise. He included another term in his *noise pollution level* (NPL) or L_{NP} .

Robinson examined the available Griffiths and Langdon data.⁵⁷ He then examined the aircraft noise

experiments of Pearsons⁵⁸ and found that L_{NP} predicted very well Pearsons's data points and the trade-off between duration and level for individual flyover events. A-weighted levels were used in L_{NP} with traffic noise, and perceived noise levels (PNdB) were used with aircraft noise. The superiority of L_{NP} over all other forms of noise rating has not been proved in practice, and it has not been widely used.

13.3 Equivalent Sound Pressure Level

Figure 16 shows the annoyance results of Pearsons and co-workers, using six different noise ratings: L_1 , L_{10} , L_{50} , L_{90} , L_{eq} , and L_{NP} .⁵⁹ As expected for all of the noise measures, annoyance increases with level. (See Chapter 25.) The shapes of the curves, however, do vary considerably when the annoyance is less than very annoying. In particular, the L_{10} and L_{eq} measures exhibit a very steep rise in annoyance from the categories of *slightly* to *moderately annoying* for no increase in noise level, presumably one of their drawbacks. However, except for the case of L_{NP} in the *extremely annoying* category, the standard deviation of L_{eq} for a specified response category was in all cases less than or equal to the standard deviation of the other noise measures. This is an advantage in the use of L_{eq} since there is more confidence in the annoyance scores predicted. There is one clear advantage of L_{eq} over L_{10} , however, in the case of noise containing short-duration, high-level single events. If the events do not occur for more than 10% of the time, then L_{10} will be relatively insensitive to these high-level events and will tend to represent the "background" noise. In fact, for a noise measure L_n to be useful, the intruding noise events must be present for *more than n%* of the time. This suggests that L_{10} would be unsuitable as a

measure of aircraft noise annoyance and that it might be a possible source of error in Griffiths and Langdon's results⁵⁷ for low traffic flows.

The A-weighted equivalent sound pressure level (often now denoted as L_{eq}) has become the measure most commonly used to assess and regulate road traffic (and railroad noise).³⁶ In the United States L_{dn} (a similar measure) is used for road traffic noise assessment.

14 EVALUATION OF COMMUNITY NOISE

In some community noise measures, corrections are applied to community noise levels to account for pure-tone components or impulsive character, seasonal corrections (summer or winter when windows are always closed), type of district (rural, normal suburban, urban residential, noisy urban, very noisy urban), and for previous exposure (such corrections are similar to those for NR).

Figure 17 gives three examples of the A-weighted sound pressure levels measured in a community over a 24-h period.³⁴ The triangles in the three figures are the maximum levels read from a graphic level recorder. The continuous lines are percentile levels measured for hour-long periods throughout the 24 h. The highest percentile measure L_1 does not represent the maximum levels well, which are presumably mostly higher level, short-duration sounds (occurring less than 1% of the time). It is observed in Fig. 17a and 17b that although the day-night levels L_{dn} are only 3 dB different (86 and 83), there is a much greater fluctuation in sound pressure level with time in Fig. 17b. This example is for a location near a major airport, and the fluctuation in level would suggest that the noise environment in location 6 would be much more annoying than in location 1 (near a freeway). Figure 17c illustrates

Figure 16 Annoyance as a function of noise level. (From Ref. 59)

Figure 17 Variation of percentile levels throughout 24 h periods recorded at three residential locations (numbers 1, 6, and 12) in Los Angeles in 1971. (a) third-floor apartment near freeway, (b) urban residential location near major airport, and (c) old residential location near city center. The values of L_n represent the A-weighted sound pressure levels exceeded n percent of the time during 1-h periods. Hourly maximum levels L_{\max} , 1-h and 24-h values of L_{eq} , and the day-night level L_{dn} are also shown. (From Refs. 34 and 39.)

another quite different distribution of A-weighted sound pressure levels with time.

In the United States, the A-weighted L_{eq} and L_{dn} are normally used to characterize community noise. However, the Department of Housing and Urban Development (HUD) also recognizes the usefulness of L_{10} in some instances. In other countries the A-weighted L_{eq} is mainly used for community noise studies rather than L_{dn} . International standards on the description and measurement of environmental noise⁶⁰ recommend the use of A-weighted L_{eq} and rating levels (which are A-weighted L_{eq} values to which tone and impulse adjustments have been made). These standards also recommend that in some circumstances it may be useful to determine the distribution of A-weighted sound pressure levels by determining percentile levels such as L_{95} , L_{50} , and L_5 .

In California, some state legislation requires the use of the *community noise exposure level* (CNEL) rather than the day-night level L_{dn} . The two descriptors are similar except that the CNEL (L_{CN}) like L_{den} has three periods instead of two. Besides the night penalty of 10 dB, an evening penalty of 5 dB is applied with CNEL. CNEL is defined⁶¹ as

$$L_{CN} = 10 \log \frac{12(10^{L_d/10}) + 3(10^{(L_e+5)/10}) + 9(10^{(L_n+10)/10})}{24} \quad (8)$$

where L_d is the average 12-h day HNL (hourly noise level), L_e is the average 3-h evening HNL, and L_n is the average 9-h night HNL.

The hourly noise level is given by

$$HNL = 10 \log \frac{\int 10^{L/10} dt}{3600} \quad (9)$$

where L is the instantaneous A-weighted sound pressure level, and t is the time in seconds. The integral

is calculated and summed. HNL is usually computed electronically. As is discussed in Chapter 106, the CNEL has also been extensively used to evaluate airport noise in California.⁶² In California it has also been used to assess environmental noise transmission into buildings (see Chapter 106).

15 HUMAN RESPONSE

15.1 Sleep Interference

Various investigations have shown that noise disturbs sleep.^{63–69} It is well known that there are several stages of sleep and that people progress through these stages as they sleep.⁶³ Noise can change the progression through the stages and if sufficiently intense can awaken the sleeper. Most studies have been conducted in the laboratory under controlled conditions using brief bursts of noise similar to aircraft flyovers or the passage of heavy vehicles. However, some have been conducted in the participants' bedrooms. Different measures have been used such as A-weighted *maximum sound pressure level* $L_{A\max}$, A-weighted *sound exposure level* (ASEL), *effective perceived noise level* (EPN dB), and *day-night sound pressure level* [DNL (L_{dn})], and most studies have concentrated on the percentage of the subjects that are awakened. Pearsons et al.⁶⁸ have reassessed data from 21 sleep disturbance studies (drawn from the reviews of Lucas⁶³ and Griefhan⁶⁴ and seven additional studies). From these data, Finegold et al.⁶⁹ have proposed sleep disturbance criteria based on the indoor ASEL. In the reanalysis, because of the extremely variable and incomplete databases, the data were averaged in 5-dB intervals to reduce variability. A regression fit to these data gave the following expression (which is also shown graphically in Fig. 18):

$$\% \text{ Awakenings} = 7.1 \times 10^{-6} L_{AE}^{3.5} \quad (10)$$

Figure 18 Proposed sleep disturbance curve based on data of Pearsons et al.⁶⁸ (From Ref. 69 with permission.) Curve represents percentage of subjects awakened against A-weighted sound exposure level ASEL.

where L_{AE} is the indoor ASEL. Although the authors recognize that there are concerns with the existing data and there is a recognition that additional sleep disturbance data are needed, Finegold et al.⁶⁹ have proposed that Fig. 18 be used as a practical sleep disturbance curve until further data become available. Sleep disturbance caused by noise is discussed in more detail in Chapter 24.

15.2 Annoyance

In 1978 Schultz published an analysis of 12 major social surveys of community annoyance caused by transportation noise.⁷⁰ This Schultz analysis, which relates the percentage of the population that report they are “highly annoyed” by transportation noise to the A-weighted day–night average sound pressure level DNL (L_{dn}), has become widely used all over the world as an important curve for describing the average community response to environmental noise. Since the Schultz curve was published, additional data have become available. Fidell et al.⁷¹ used 453 exposure response data points compared to the 161 data points originally used by Schultz. This resulted in almost tripling the database for predicting noise annoyance from transportation noise. A later study by the U.S. Air Force eliminated 53 of these data points because there was insufficient correlation between the DNL and the percentage of the population that was highly annoyed, %HA.⁶⁹ The results of these two studies and the original Schultz curve are given in Fig. 19. Finegold et al.⁶⁹ recommend a logistic fit,

$$\%HA = \frac{100}{1 + \exp(11.13 - 0.14L_{dn})} \quad (11)$$

rather than the quadratic fit used by Fidell et al.⁷¹ or the third-order polynomial fit used by Schultz.⁷⁰ This

Figure 19 Curves representing the percentage of subjects that are highly annoyed by noise against A-weighted day–night average sound pressure level DNL (L_{dn}): (—■—) New logistic USAF curve (400 data points), (...+...) Schultz⁷⁰ third-order polynomial (161 data points), and (---*) Fidell et al.⁷¹ quadratic curve (453 data points). (From Ref. 69 with permission.)

results in a very close agreement between the curve obtained with the 400 data points and the original 1978 Schultz curve.⁷⁰ See Fig. 20. The differences between the curves in Figs. 19 and 20 are not very significant; however, there are several advantages to the use of the logistic fit given in Eq. (11), including (1) the same predictive utility in both the original Schultz curve

Figure 20 Curves representing the percentage of subjects that are highly annoyed by noise against A-weighted day–night average sound pressure level DNL (L_{dn}). (—■—) Logistic fit to 400 community annoyance social survey data points and (...+...) 1978 Schultz⁷⁰ curve. (From Ref. 69 with permission.)

and the Fidell et al. curve, (2) it allows prediction of annoyance to approach but does not reach 0 or 100%, (3) it approaches a 0% community annoyance prediction for a DNL (L_{dn}) of approximately 40 dB rather than the anomaly of an increase in annoyance for levels of less than 45 dB as predicted by the Fidell et al. curve, (4) use of a logistic function has had a history of success with U.S. federal environmental impact analyses, and (5) it is based on the most defensible social survey database.⁶⁹

Most community noise impact studies since the late 1970s have been based on a combination of aircraft and surface transportation noise sources. However, there has been a continuing controversy over whether all types of transportation should be combined into one general curve for predicting community annoyance to transportation noise.^{69,72-78} Some researchers have suggested that people find aircraft noise more annoying than traffic noise or railroad noise for the same value of DNL.^{36,69,72,76}

The differences have been discussed in the literature^{36,39,69} and can perhaps be explained by a variety of causes such as (1) methodological differences, (2) variability in the criterion for reporting high annoyance, (3) inaccuracy in some of the acoustical measurements, (4) community response biases, and (5) aircraft noise entering homes through parts of the building structure with less transmission loss (such as the roof rather than the walls with aircraft noise). Figure 21 shows logistic fits to 400 final data points from a total of 22 different community annoyance surveys. It can be seen that aircraft noise appears to produce somewhat more annoyance than railroad or traffic noise particularly for the higher DNL (L_{dn})

Figure 21 Curves representing the percentage of subjects that are highly annoyed by noise against A-weighted day-night average sound pressure level DNL (L_{dn}) for different sources: ■ Aircraft, ...+... traffic, and --*-- railway. Curves based on data from Fidell et al.⁷¹ (From Ref. 69 with permission.)

values. Miedema and Vos have made a reanalysis of data from selected social surveys that also shows that aircraft noise appears to cause more annoyance than other surface transportation noise sources.⁷² However, the results from the Miedema and Vos study seem to suggest that for high values of DNL (L_{dn}) (over 60 to 70 dB), although aircraft noise is by far the most annoying source, railroad noise is also more annoying than traffic noise (in contrast to the results of Finegold et al).⁶⁹

If the five causes discussed above can be dismissed as responsible for the apparent greater annoyance of aircraft noise, then it may be that aircraft noise is more annoying than surface transportation noise for reasons such as: (1) the higher peak levels, (2) the greater variation in level with time, and (3) the different frequency spectra from other types of transportation noise sources. As already discussed in the text accompanying Fig. 17, aircraft noise does generally exhibit a much greater variation in level from traffic noise and other sources of surface transportation. If such variation is indeed more annoying and is one of the main causes of the difference in annoyance caused by these different forms of transportation noise, this suggests that it may be advisable to reexamine such measures that account for variation in level such as the TNI or the NPL discussed in Sections 13.1 and 13.2. The annoyance caused by noise is discussed in more detail in Chapter 25 and also briefly in Chapter 119.

16 NOISE CRITERIA AND NOISE REGULATIONS

Using some of the noise measures and descriptors discussed and surveys and human response studies, various criteria have been proposed so that noise environments can be determined that are acceptable for people, for speech communication, for different uses of buildings, for sleep, and for different land uses. In some countries such criteria are used to write noise regulations for new machinery, vehicles, traffic noise, railroad noise, aircraft and airport noise, community noise, and land use and planning. It is beyond the scope of this chapter to give a comprehensive summary of all these criteria and regulations. Instead just a few are described in this section. The interested reader is referred to the chapters in Part VIII and to the literature^{36,39,73} for more complete summaries of criteria, regulations, and legislation. For instance, Chapter 120, provides information on limits for the noise of new vehicles in different countries (where acceleration noise tests are used). Such limits are based on results such as those presented in Fig. 7.

16.1 Noise Criteria

An example of noise criteria is given in Table 2, which is based on those suggested by Beranek and Ver²³ and gives recommended NCB curve values (and approximate A-weighted levels) for various indoor functional activity areas. The NCB curves are given in Fig. 13. For example, the air-conditioning unit

Table 2 Recommended Values of NCB Curves for Different Uses of Spaces in Buildings^a

Type of Space (and Acoustical Requirements)	NCB Curve	Approximate L_A
Broadcast and recording studios	10	18
Concert halls, opera houses, and recital halls	10–15	18–23
Large auditoriums, large drama theaters, and large churches	<20	28
Broadcast, television, and recording studios	<25	33
Small auditoriums, small theaters, small churches, music rehearsal rooms, large meeting and conference rooms	<30	38
Bedrooms, sleeping quarters, hospitals, residences, apartments, hotels, motels, etc.	25–40	38–48
Private or semiprivate offices, small conference rooms, classrooms, and libraries	30–40	38–48
Living rooms and drawing rooms in dwellings	30–40	38–48
Large offices, reception areas, retail shops and stores, cafeterias, and restaurants	35–45	43–53
Lobbies, laboratory work spaces, drafting and engineering rooms, general secretarial areas	40–50	48–58
Light maintenance shops, industrial plant control, rooms, office and computer equipment rooms, kitchens, and laundries	45–55	53–63
Shops, garages, etc. (for just acceptable speech and telephone communication)	50–60	58–68
For work spaces where speech or telephone communication is not required, but where there must be <i>no risk</i> of hearing damage	55–70	63–78

^aAlso given are the approximate equivalent A-weighted sound pressure levels L_A .

chosen to supply air to bedrooms (used in residences, apartments, hotels, hospitals, etc.) should have a spectrum corresponding to no more than an NCB curve of 25 to 40 (or an A-weighted sound pressure level of no more than about 38 to 48 dB).

Another example of noise criteria are the guidelines recommended by EPA,³⁸ WHO,⁷⁵ FICON,⁴⁰ and various European road traffic regulating bodies. See Table 3. As already mentioned, L_{eq} is very widely used to evaluate road traffic, railroad, and even aircraft noise.³⁶ Interestingly, railroad noise has been found to be less annoying than traffic noise in several surveys.^{36,79,80} This has resulted in noise limits (using L_{eq}) that are 5 dB lower for railroad noise than road traffic noise in Austria, Denmark, Germany, and

Switzerland and 3 dB lower in The Netherlands.³⁶ Gottlob terms this difference the “railway bonus.”³⁶

An example of national noise exposure criteria is the guidance given in the British government guidelines adopted in 1994 for land development given in Table 4. This table shows guidelines in A-weighted sound pressure levels L_{eq} for four noise exposure categories.⁸¹ The noise exposure categories can be interpreted as follows⁸²: (a) Noise need not be considered as a determining factor in granting planning permission, although the noise level at the high end of the category should not be regarded as a desirable level; (b) noise should be taken into account when determining planning applications, and where appropriate, conditions should be imposed

Table 3 Guidelines from EPA,³⁸ WHO,⁷⁵ FICON,⁴⁰ and Various European Agencies for Acceptable Noise Levels

Authority	Specified A-Weighted Sound Pressure Levels	Criterion
EPA levels	$L_{dn} \leq 55$ dB (outdoors)	Protection of public health and welfare with adequate margin of safety
Document ³⁸	$L_{dn} \leq 45$ dB (indoors)	
WHO	$L_{eq} \leq 50/55$ dB (outdoors; day)	Recommended guideline values
Document (1995) ⁷⁵	$L_{eq} \leq 45$ dB (outdoors; night)	
	$L_{eq} \leq 30$ dB (bedroom)	
	$L_{max} \leq 45$ dB (bedroom)	Considered generally compatible with residential development
U.S. Interagency Committee (FICON) ⁴⁰	$L_{dn} \leq 65$ dB	
	$65 \leq L_{dn} \leq 70$ dB	Residential use discouraged
Various European road traffic regulations ³⁶	$L_{eq} \geq 65$ or 70 dB (day)	Remedial measures required

Source: Based on Ref. 39.

Table 4 Guidelines Used in the United Kingdom for A-Weighted Equivalent Sound Pressure Levels for Different Noise Exposure Categories

Noise Source		Noise Exposure Category			
		A	B	C	D
Road traffic	(07.00–23.00)	<55	55–63	63–72	>72
	(23.00–07.00)	<45	45–57	57–66	>66
Rail traffic	(07.00–23.00)	<55	55–66	66–74	>74
	(23.00–07.00)	<45	45–59	59–66	>66
Air traffic	(07.00–23.00)	<57	57–66	66–72	>72
	(23.00–07.00)	<48	48–57	57–66	>66
Mixed sources	(07.00–23.00)	<55	55–63	63–72	>72
	23.00–07.00)	<45	45–57	57–66	>66

to ensure an adequate level of protection against noise; (c) planning permission should not normally be granted; where it is considered that permission should be given, for example, because there are no alternative quieter sites available, conditions should be imposed to ensure a commensurate level of protection against noise; and (d) planning permission should normally be refused.^{83,84}

17 HUMAN VIBRATION CRITERIA

The effects of vibration on people are reviewed in Chapter 29. Different criteria are needed for vibration in buildings, vehicles, and that caused by the use of machine tools. Work continues on such effects of vibration on people and criteria for human comfort and protection.^{85–87}

CHAPTER 35

GENERAL INTRODUCTION TO NOISE AND VIBRATION TRANSDUCERS, MEASURING EQUIPMENT, MEASUREMENTS, SIGNAL ACQUISITION, AND PROCESSING

Malcolm J. Crocker
Department of Mechanical Engineering
Auburn University
Auburn, Alabama

1 INTRODUCTION

In the measurement of noise and vibration fields, it is necessary to sense the sound or vibration disturbance with a transducer. The transducer converts some physical property of the sound and vibration field into an electrical signal. This signal is then amplified, attenuated, or transformed in some way so that it can be analyzed and/or processed to provide the data of particular interest. For some cases such as simple measurements of the A-weighted sound pressure level, only limited amounts of processing are needed. In other cases with more sophisticated measurements, special analysis and processing is required. Such examples include modal analysis, sound intensity, wavelet analysis, machinery condition monitoring, and acoustical holography, with which quite complicated signal analysis and processing may be needed. In all cases considerable care should be taken to ensure that the transducers together with their measurement systems are calibrated and checked periodically to make sure they are working properly. Part V of this book contains 19 chapters concerned with the basic design principles of noise and vibration transducers, analysis equipment, signal processing, and simple and advanced measurement techniques for various noise and vibration measurements, including those for source and path identification.

2 TYPICAL MEASUREMENT SYSTEMS

It may be necessary to measure noise and/or vibration for various different reasons. Before beginning any measurement program, the objectives should be defined. For instance, it may be desired to measure noise to determine if a noise problem exists, whether the noise output of a machine is within its specifications, to determine the main sources of noise on a machine or in a vehicle or building. In the case of vibration, the reasons for measurement can include determining whether vibration of structures may result in unwanted sound generation, or in the case of intense vibration, machine wear and condition, and even the danger of structural fatigue and failure. The basis of all noise and vibration measurement systems is the transducer. The microphone is the main transducer

used to measure sound, while the accelerometer is the main transducer used to measure vibration. Specialized transducer systems have been developed to measure sound intensity in air and vibration intensity of structural systems. In addition, measurement procedures have been formulated to determine the modes of vibration of structures. Special rooms and systems such as anechoic and reverberant rooms and impedance tubes (see Chapter 43) are now widely used for sound power and noise source identification measurements of machines and the measurement of the acoustical impedance of materials. With any measurement, calibration of the system is essential to obtain reliable results that can be compared with results obtained by others.

Since about 1920, most sound and vibration measurement systems have made extensive use of electrical networks. From that time, the electrical amplification of signals has made possible several measurement techniques that were previously impossible to use. When measurements are made of noise or vibration, it is usually necessary to combine several different types of instruments into one measurement system. The individual components of the measuring system utilized will depend on the particular measurements needed. A generalized system is shown in Fig. 1. To design a system to make useful measurements, it is desirable for one to have a good understanding of the phenomena being investigated and to have a reasonable understanding of the functioning of the instrumentation and signal processing. The chapters in Part V of this book are designed to help with these requirements. Chapter 43 reviews some of the noise and vibration measurements in common use, uncertainty concerns with the measured results, and some of the more specialized procedures for measuring the passby noise of vehicles and the flyby noise of aircraft.

The first item in any noise or vibration measuring system is the *transducer*. As its name implies, this instrument converts a signal in one physical form into another, that is, a transducer converts a sound pressure signal or a vibration signal into an electrical signal. Normally, the electrical signal obtained from a transducer is not suitable for direct analysis or readout, and a *signal conditioner* is then used to amplify,

Figure 1 Idealized noise or vibration measuring system.

attenuate, or transform the signal using analog-to-digital (A/D) conversion. It is optional at this stage to include a *data storage* item in the system before the signal is passed to a *signal processor*. (See Fig. 1.) The signal processor may consist of a narrow-or wide-band filter, a root-mean-square (rms) detector, a probability density analyzer, and the like. See Chapter 40 for more details of signal analysis equipment and systems. The last item in the system is usually the *display unit*, a read-out unit, or a digital computer, which is used to perform some postprocessing of the signal. Analog and/or digital meters, oscilloscopes, and other units can all be used to display signals. Also a data storage item or data distribution system can be included in the main measurement system at this stage instead of earlier, so that the data can be analyzed or shared with others later. (See Chapter 41.)

3 TRANSDUCERS

Transducers and their associated measuring systems generally suffer from two major shortcomings:

1. A transducer will normally respond to other variables in addition to its response to the variable of interest. For example, a microphone, although being most sensitive to sound pressure, may also be slightly sensitive to variations in temperature, humidity, magnetic fields, and vibration.
2. It is difficult, and in many cases not possible, to introduce a transducer into the measurement medium without disturbing the medium in some way. The transducer will extract some energy from the medium or structural system. In addition, other disturbances will be caused. An accelerometer will add mass to the system and alter the structure's vibration. A pitot tube or hot-wire anemometer will disturb the flow. A microphone will reflect, diffract, and refract the incident sound wave. Some noncontacting vibration transducers and systems will not

directly interfere with the vibration of the system to be measured, but they will interfere with any associated sound field generated by the vibrating body.

3.1 Transducer Characteristics

An ideal sound or vibration transducer should have the following characteristics¹:

1. It should cause negligible diffraction of the sound field or structural vibration field (i.e., its dimensions should be small compared with the smallest sound or vibration wavelength of interest).
2. It should have a high acoustical or mechanical (driving point) impedance compared with the fluid medium or structure so that little energy is extracted from the field.
3. It should have low electrical noise.
4. Its output should be independent of temperature, humidity, magnetic fields, static pressure, and wind velocity, and it should be rugged and stable with time.
5. Its sensitivity should be independent of sound pressure or vibration level magnitudes.
6. Its frequency response should be flat.
7. It should introduce a zero phase shift between the sound pressure or structural vibration and the electrical output signal.

No transducer can meet all of the above criteria, and thus different types of transducers and vibration sensors are preferred for different measurements. The microphone is by far the most common form of acoustical transducer, and the piezoelectric accelerometer is the most widely used vibration transducer. Because of their importance the next section of this chapter concerns these devices. But it should be noted that other specialized noise and vibration transducers are used for measurements. For instance, sound intensity probes of

different designs can be used for noise source identification and sound power measurements of a source in situ (see Chapters 36 and 45), and several other types of vibration-measuring transducers such as strain gauges and laser Doppler interferometer systems are also in use, as described in Chapter 37.

3.2 Sensitivity

An ideal microphone (or accelerometer) together with its measurement system should have an output voltage amplitude E that is proportional to the exciting pressure amplitude p (or acceleration amplitude a) (see Fig. 2). The ratio of open-circuit output voltage to input pressure (or acceleration) is normally called the sensitivity M_p :

$$M_p = E/p \quad \text{or} \quad M_p = E/a \quad (1)$$

The transducer sensitivity [V/(N/m²) or V/(m/s²)] depends on the microphone (or accelerometer) design. (Different types are discussed in Chapters 36 and 37 and later in Sections 4.1, 5.1, and 5.2 of this chapter.)

In the case of noise measurements with very low sound pressure amplitudes, electrical noise will exceed the voltage signal generated by the microphone, and this will govern the lower signal amplitude limit for measurements. With very high sound pressure amplitudes, the diaphragm displacement may become so large that the voltage generated is no longer proportional to the displacement. Nonlinearity then sets the upper amplitude use limit. See Chapter 36. For sound pressures somewhat above the nonlinear limit, physical damage to the microphone can occur.

The situation is similar for vibration measurements made with seismic mass accelerometers. For very high vibration amplitudes, the accelerometer displacement may become so large that the voltage generated is no longer proportional to the displacement. Nonlinearity again sets an upper use limit. For displacements above the nonlinear limit, physical damage to the accelerometer can occur. Large accelerometers are normally more sensitive than small ones, and this is advantageous in many applications; but large heavy accelerometers cause more mass loading problems

Figure 2 Sensitivity of (1) an ideal microphone or accelerometer _____ and (2) an actual transducer •.

to start to occur at a lower frequency than small lightweight accelerometers.¹

If Fig. 2 is plotted on a logarithmic scale, Fig. 3 is obtained. The reference voltage E_{ref} is normally taken as 1 V, while the reference sound pressure p_{ref} is usually taken as 20 μPa , and the reference acceleration is normally taken as 1 $\mu\text{m/s}^2$.

A microphone or accelerometer has a usable range of operation between its upper and lower amplitude limits. Thus, at any frequency the *microphone or accelerometer response magnitude* is normally given by subtracting the X from the Y axis in Fig. 3, and the range ΔR in which the microphone or accelerometer response R is constant is known as the dynamic range:

$$\begin{aligned} R &= 20 \log \left(\frac{E/p}{E_{\text{ref}}/p_{\text{ref}}} \right), \text{ dB} \\ &= 20 \log \left(\frac{E/E_{\text{ref}}}{p/p_{\text{ref}}} \right), \text{ dB} \end{aligned} \quad (2a)$$

or

$$\begin{aligned} R &= 20 \log \left(\frac{E/a}{E_{\text{ref}}/a_{\text{ref}}} \right), \text{ dB} \\ &= 20 \log \left(\frac{E/E_{\text{ref}}}{a/a_{\text{ref}}} \right), \text{ dB} \end{aligned} \quad (2b)$$

3.3 Dynamic Range

It is seen for the microphone (or accelerometer) shown in Fig. 3 that the dynamic range is about 100 dB. Most good-quality microphones have a dynamic range of about 100 to 120 dB (interestingly enough about the same as the human ear). See Chapter 36. As the microphone diaphragm diameter (or accelerometer mass) is increased, the transducer sensitivity is normally increased as well so that electrical noise is less of a problem and the lower signal amplitude limit for measurements is decreased. In the case of a microphone, however, a larger diaphragm diameter usually results in a larger deflection for a given sound pressure and a reduced upper sound pressure level limit because of nonlinearity problems. Thus between the upper and lower amplitude limits the microphone has a usable range of operation.

Small-diameter microphones are not very sensitive but can be used for high-amplitude sound pressures without distortion; their electronic noise floor is quite high, however. (Different types are discussed briefly in this chapter. The fundamentals of the operation of the main types of microphone are described in more detail in Chapter 36.) Large-diameter microphones are normally more sensitive and can be used for lower level noise than small-diameter microphones. Their noise floor is lower, but larger diameter microphones experience more diffraction problems at low frequencies than small-diameter microphones.¹ Figure 4 shows the inherent noise floor plotted against upper limiting frequency for four microphone diameters.² Because of the dynamic range problems, the small-diameter microphones cannot be

Figure 3 Sensitivity of an ideal microphone or accelerometer showing upper and lower limits.

Figure 4 Inherent noise floor against upper limiting sound pressure level for four different diameter microphones. The four dots represent the four sizes of microphone (1 in., $\frac{1}{2}$ in., $\frac{1}{4}$ in., and $\frac{1}{8}$ in.) in order from 1 in. (bottom left) to $\frac{1}{8}$ in. (top right).²

used for very “quiet” sounds, and the large-diameter microphones cannot be used for intense noise.

Figure 5 shows the dynamic range for four commercially available microphones. The lower level limit is given in terms of the A-weighted sound pressure

level of the internal noise floor of the microphone and associated preamplifier. The upper level limit is set by the sound pressure level at which 3% dynamic distortion occurs. It is observed that the 1-in. and $\frac{1}{2}$ -in. diameter microphones have the greatest dynamic ranges of about 150 dB. The $\frac{1}{4}$ -in. microphone has a dynamic range of about 140 dB, while the $\frac{1}{8}$ -in. diameter microphone has a dynamic range of only about 100 dB.²

3.4 Frequency Response

The *magnitude of the frequency response*, $R(f)$, of an ideal microphone is given by Eq. (2a) as the frequency of the sound pressure p is changed. The *magnitude of the frequency response*, $R(f)$, of an ideal accelerometer is given by Eq. (2b) as the frequency of the vibration a is changed. Figure 6 shows the frequency response of an ideal microphone used for noise measurements or an ideal accelerometer used for vibration measurements. In practice microphones and accelerometers can only approach the ideal frequency response in Fig. 6. Resonance peaks of the diaphragm of the microphone or the inertial mass of the accelerometer are usually observed in the high-frequency range. These peaks are normally

Figure 5 Comparison of the dynamic ranges of the same four condenser microphones as shown in Fig. 4. The lower limit is A-weighted sound pressure level. The upper limit is given in decibels at which 3% total harmonic distortion occurs.²

suppressed by the addition of damping or some other means at the transducer design stage. Note that for some measurements (e.g., explosive blasts with a microphone and shock events with an accelerometer) knowledge of the phase frequency response of the transducer is also important. For such measurements of impulsive phenomena, the additional requirements of zero or linear phase shift with frequency are needed for microphones and accelerometers, respectively.

Figure 7 shows the frequency response range of four different diameter condenser microphones.² It is

observed that the smaller diameter microphones have the largest usable frequency range. The $\frac{1}{8}$ -in. diameter microphone has a usable range from about 5 Hz to about 150 kHz. The 1-in. microphone on the other hand has a much more restricted usable frequency range from about 2 Hz to only about 10 kHz.

4 NOISE MEASUREMENTS

Since the human hearing range extends from about 20 to 20,000 Hz, it is desirable that the frequency response of microphones and noise measurement systems should be “flat” between these limits as shown in Fig. 6. For certain types of measurements (e.g., for measurement of sonic booms or explosive blasts), it may be necessary to measure sounds that contain frequencies lower than about 20 Hz. For scale-model studies or for the measurement of noise environments or structures subject to fatigue, it may be necessary to measure to frequencies higher than 20,000 Hz. We will first discuss the different types of microphones used in noise measurements and their acoustical properties and then methods by which microphones are calibrated. More details about microphones are given in Chapter 36 and of their calibration in Chapter 51. Chapter 57 in the *Handbook of Acoustics*³ also has detailed information about microphone calibration.

Figure 6 Frequency response of an ideal microphone or accelerometer.

Figure 7 Comparison of the frequency response ranges of four different diameter condenser microphones [lower limiting frequency (Hz) and upper limiting frequency (kHz)]. Microphone diameters: $\frac{1}{8}$ in., $\frac{1}{4}$ in., $\frac{1}{2}$ in., and 1 in.²

4.1 Types of Microphones for Noise Measurements

An acoustical transducer is a device that converts some property of a sound field into an electrical signal. The most common device is the microphone designed to measure sound pressure. Some transducers have been designed, however, to measure sound particle velocity, sound pressure gradient, and sound intensity.

Microphones may be divided into three main classes: communication, studio, and measurement microphones. (See Chapter 36 for more details.) The discussion here mainly concerns noise measurement microphones. There are three main types of microphone used for noise measurements: (1) polarized condenser microphones, (2) prepolarized condenser microphones (sometimes called electret microphones), and (3) piezoelectric microphones. The polarized condenser microphone possesses a thin diaphragm under tension and must be provided with an external polarizing voltage that is applied between the diaphragm and the backplate. On the other hand, the prepolarized condenser (electret) microphone avoids the need for a polarizing voltage by the provision of a thin layer of electrically charged material, which is normally deposited on the backplate during manufacture.

Condenser microphones, because of their stability and well-defined mechanical impedance, are the ones mostly preferred for noise measurements. They do have drawbacks of fragility and sensitivity to humidity, however. Piezoelectric microphones are more robust than condenser microphones. They possess a stiff diaphragm that is coupled to a piezoelectric crystal or ceramic element.

Microphones may be divided into directional and nondirectional (or omnidirectional) types. In some cases, directional microphones may be useful, such as in the localization of noise sources. Most noise measurements are made with nominally omnidirectional microphones, although even these types become somewhat directional at high frequency, at which the dimensions of the microphone become comparable with the acoustic wavelength.

Microphones may be further subdivided into three main types: (1) free-field, (2) pressure-field, and (3) diffuse-field microphones. The frequency responses of these microphones are adjusted so that they have an essentially flat frequency response when placed in these different sound fields. Today TEDS (transducer electronic data sheet) microphones with built-in sensitivity are also available. These microphones have built-in information about the response required in different sound fields. So such TEDS microphones can be used in all of the three sound fields described above if they are used in conjunction with information loaded into the operating system of the associated analyzer. Chapter 36 describes the design and principles of operation of the main types of microphones and furthermore explains how the microphone parameters, physical properties, and design may be chosen to obtain the required microphone sensitivity, frequency response, and dynamic range. Chapter 43 also addresses some of the same considerations with respect to noise measurements.

4.1.1 Condenser Microphones The introduction, in the 1920s, of the condenser microphone with its uniform sensitivity, low distortion, and portability revolutionized electroacoustics, and it soon became an integral part of any high-quality sound system. However, although the polarized condenser microphone has significant advantages, it also suffers from some disadvantages: specifically its rather low sensitivity, high internal impedance, and the need for a polarizing voltage. These shortcomings led to the development of other microphone designs such as piezoelectric and prepolarized types, which will be discussed shortly and also in more detail in Chapter 36. The very large, almost distortionless electronic signal amplification that can now be achieved has made the lack of sensitivity of the condenser microphone unimportant, and, because of its smooth sensitivity over a very wide frequency range and its well-defined geometry, the condenser microphone is still preferred for use in many noise measurement applications.⁴

Figure 8 shows a diagram of a 1-in. condenser microphone. The condenser microphone consists of a thin metal diaphragm stretched under tension and spaced a short distance from an insulated backplate. The diaphragm and backplate constitute the electrodes of the condenser. Holes are drilled in the backplate to provide the required air damping for the diaphragm. A small hole is provided to equalize the static pressure across the diaphragm, provided that it changes slowly. This hole usually determines the lower cutoff frequency of the microphone. Some discussion of the electrical circuit of the system and the theory, design, and construction of condenser microphones is given in Chapter 36 and in Chapters 110 and 112 of the *Handbook of Acoustics*.³ Other authors have also discussed the electrical theory in some detail.⁵⁻⁷ It is normally necessary to remove the protection grid during microphone calibration (see Chapter 51).

4.1.2 Prepolarized (Electret) Microphones In the 1970s, a new type of precision microphone became commercially available. This microphone is basically a condenser microphone; however, no direct current (dc) polarization voltage is needed since the electret foil diaphragm and/or the backplate is permanently polarized during manufacture. The polarization voltage is created by embedding and aligning static electrical charges into a thin layer of material, which is deposited on the microphone diaphragm or backplate.

The first electret microphones used diaphragms made from an insulating material that carried the permanent electrical charge. The diaphragms of electret microphones made in this way have to be quite heavy in order to carry the permanent electrical charge material. Heavy diaphragms have several disadvantages and result in a low resonance frequency peak. Most high-quality electret microphones used for noise studies now have the permanently charged material attached to the stationary backplate instead of the diaphragm. In this way, much thinner diaphragms can be used, made of the same metal-coated plastic material used in condenser microphones. Such microphones have a

Figure 8 Cross section through a 1-in. condenser microphone.

high resonance frequency peak and an overall performance almost rivaling the best condenser microphone. The thin diaphragm and the perforated backplate comprise the two plates of the condenser. Preamplifiers are still needed, and in some recent electret microphones miniature preamplifiers are built into the microphones themselves. See Chapter 36 and Chapters 110 and 112 of the *Handbook of Acoustics*.³ Figure 9 shows a cross-sectional diagram of a typical electret microphone.⁸

The electret microphone has the following advantages: (a) no polarization voltage needed, (b) rugged construction, (c) large capacitance (about 500 pF), and hence, loading is a lesser problem than with the condenser microphone), and (d) low cost.^{6,9,10}

4.1.3 Piezoelectric Microphones The design and construction of piezoelectric transducers is discussed in Chapter 36 and in Chapters 110 and 112 in

Figure 9 Electret microphone using a thin electret polymer layer deposited on the perforated backplate.

the *Handbook of Acoustics*³ and in varying detail by several other authors.^{11,12}

Piezoelectric crystals may be cut and used in many different orientations. If a slice is cut from a piezoelectric crystal and pressures applied to the opposite faces of the slice causing a deformation, then equal and opposite charges are produced on the opposite faces of the slice with an electric potential developed between the faces. Crystals are often directly exposed to liquids (e.g., as hydrophones) where the high mechanical impedance of the liquid is not a disadvantage. In gases, the large acoustical/mechanical impedance mismatch is a disadvantage, and piezoelectric materials are usually used in conjunction with a diaphragm. See Chapter 36.

Figure 10 shows a cross-sectional view of a commercial piezoelectric microphone. Much thicker diaphragms are normally used with piezoelectric than condenser microphones (usually about 50 times greater). This inevitably leads to a lower resonance frequency for the diaphragm (assuming the density of the diaphragm material is the same) [consider Eq. (10) in Chapter 1]. To obtain a flat free-field response, it is necessary to damp this resonance overcritically. Hence the upper frequency response is poorer than with a condenser microphone because the mass-controlled region is entered at a lower frequency (see Fig. 9 in Chapter 1 and Chapter 36).

The diaphragm is connected to a ceramic bender element. A bimorph simply supported bender element is most often used, although sometimes cantilever benders are used.^{11,12} The force needed to produce a voltage from a crystal or ceramic slice in pure compression is quite large. However, if a thin bar or beam is cut from a crystal in a suitable orientation, a voltage is produced across the beam as it is bent.¹ Metal foil is usually cemented to the outside surfaces

Figure 10 Cross-sectional view of piezoelectric microphone.

of the crystal, and the two foils with the crystal in between form a condenser of the solid dielectric type. It is usual to use two bars in conjunction to produce a *bimorph*. Electrical connections may be applied in two ways to the bimorph to produce either parallel or series connections.¹

Other microphones are used for many communication purposes but not normally for precision noise measurements. The moving coil microphone has been in use for many years but is less valuable in noise work since its frequency response is not very smooth and is poor at high frequencies. Also its sensitivity is low. However, it does have some advantages that make it ideal for some applications. (See Chapter 36.)

4.2 Directivity

At low frequencies, for example, below about 1000 Hz, the frequency response of a microphone is independent of the angle of incidence of the sound waves. However, at higher frequencies, as the microphone dimensions and the wavelength of the sound become comparable, *diffraction* effects become important and the frequency response of a microphone is strongly dependent on the angle of incidence of the sound. See Fig. 11. The effect of *directivity* is discussed in detail in Chapter 36 and Chapter 3 in Ref 1.

Microphones can be designed to have a flat frequency response when exposed to a free progressive wave sound field. They are usually known as free-field microphones. Other microphones can be designed to have a flat frequency response to grazing incidence sound waves and are normally known as pressure-field microphones. Still other microphones are designed to have a flat frequency response to random incidence sound and are known as diffuse-field incidence microphones. (See Chapters 36 and 43.) Care must be made

in ensuring that the right type is used. Figure 12 illustrates the use of different types.

4.3 Transducer Calibration

It is important to calibrate transducers used for sound, shock, and vibration to ensure the accuracy of measurements made with them. Proper calibration also ensures that the results measured with the transducers are comparable with the results measured by others. The accuracy of the calibration must also be known. The transducer system and the calibration method used must perform the calibration with a known accuracy. If these conditions are met, then the calibration is termed as traceable. It should be noted, however, that this traceability is not an indication necessarily of highly accurate measurements, but simply that if the uncertainty is known, the measurements can then be compared with valid measurements made by others, which have also been made using proper calibration procedures. Thus measurements made with transducers and calibration procedures are of no use unless the associated uncertainty in measurement is also known. New and upgraded international standards now provide a variety of calibration methods together with their suitability for ensuring traceability.

Transducers should be calibrated on site before and after each measurement or set of measurements and periodically at service centers or national metrology laboratories. Chapter 51 describes calibration procedures for microphones and sound intensity systems. Chapter 52 discusses the calibration of shock and vibration transducers. Chapters 51 and 52 also describe the traceability of sound and vibration measurements, and Chapter 53 describes the traceability of shock and vibration measurements to national and international standards in detail.

Figure 11 Directivity of a microphone with a protection grid at different frequencies.

Figure 12 Noise measurements using (a) free-field microphone and (b) diffuse-field microphone.

Microphones, calibrators, and sound level meters all need to be calibrated. The most common requirement is the calibration of microphones for their sound pressure response, but calibrations for sound intensity, sound power, and acoustic impedance measurements are also commonly needed. Chapter 51 discusses the calibration of microphones in detail. Nedelitsky in Chapter 108 of the *Handbook of Acoustics*³ and others have also discussed the problems of calibrating microphones. When a microphone is introduced into a sound field, it causes undesirable reflections and hence changes the sound field. This effect is more pronounced at high frequency. Ideally we should like to measure the sound pressure in the unperturbed or “free field,” but this is difficult. It is extremely important that manufacturers and users calibrate microphones accurately. Unfortunately, some users do not calibrate microphones sufficiently frequently to ensure the accuracy of sound pressure level readings. As already discussed, microphones may be designed to have three flat frequency responses. As mentioned before, TEDS microphones with built-in sensitivities are also available. TEDS microphones can be used to obtain all of the three flat frequency responses. The two main types of microphones in use are the *free-field* type (primarily used for outdoors measurements) and the *diffuse-field* type (mainly used for indoors measurements). Pressure-field microphones are mostly used for coupler measurements, except for the recently developed flat surface microphone.

As regards calibration of microphones, the pressure response may be considered to be the response of the microphone to a uniform pressure applied over its diaphragm. This is the response of an ideal microphone of *zero size* introduced into a free progressive plane wave field. However, when an actual finite size microphone is introduced into such a field, reflection and diffraction are caused, which give a different microphone response called the *free-field* response. See Chapter 36. Because the microphone can be oriented at any arbitrary angle in the plane wave field, perhaps the pressure response is more fundamental. There are several ways of measuring the pressure response of a microphone:^{13,14} (a) pistonphone, (b) driven-diaphragm-type calibrator, (c) electrostatic actuator, (d) reciprocity method, and (e) substitution method. The only absolute method of calibration is the reciprocity method. This is somewhat complicated and time consuming; and the other four methods, although not giving absolute calibration, are more convenient and normally sufficiently accurate. See Chapter 51 in this handbook and Chapter 108 in the *Handbook of Acoustics*.³

4.3.1 Pistonphones The pistonphone is a very accurate, reliable, and simple device for calibrating a microphone that is convenient for use in the field. The principle of operation is quite simple. A small battery-powered electric motor drives a shaft on which is mounted a cam disk. The cam disk drives two pistons symmetrically. The cam gives the pistons a sinusoidal motion at four times the shaft rotational speed. The

stroke of the pistons (or peak amplitude from mean position) is thus one quarter of the difference in maximum and minimum diameters of the cam. The pistons vary the cavity volume sinusoidally in time and since for pistonphones a low frequency (e.g., 250 Hz) is normally chosen (for mechanical reasons), a corresponding sinusoidal variation in pressure occurs. (See Chapter 51 and Chapter 3 in Ref. 1 for the theory and further details of its operation.)

Provided the piston stroke is carefully controlled, the sound pressure level produced can be accurately predicted. Good sealing should be maintained when the microphone is fitted into the coupler opening. In principle, this type of pistonphone can be used to calibrate any microphone provided that good sealing is maintained. If microphones of different diameters are to be calibrated with the pistonphone, and different coupler connections are used to keep the volume unchanged, the sound pressure level is unchanged. If a different volume results, the change in sound pressure level can be predicted. (See Ref. 1 for the theory.) A change in atmospheric pressure will alter the calibration, but a correction is simply made by the use of a barometer provided by the manufacturer.

4.3.2 Driven-Diaphragm Calibrators Somewhat simpler, lower cost calibrators are also available that work on the driven-diaphragm principle. Some commercially available types produce 114 dB at 1000 Hz. A stabilized 1000-Hz oscillator feeds a piezoelectric driven element that vibrates the metallic diaphragm creating a pressure in the front coupling. The diaphragm is driven by an oscillator powered by a 9-V battery. Some calibrators generate five selected frequencies: 125, 250, 500, 1000, and 2000 Hz at 94 dB. With such calibrators, corrections should normally be made for changes in ambient temperature and pressure (altitude). Newer types of calibrator have a built-in microphone that measures and controls the sound pressure generated in the coupler cavity via a feedback loop. See Chapter 51 for more details of such driven-diaphragm-type calibrators.

4.3.3 Sound Intensity Probe Calibration When two phase-matched microphones are used together to form a sound intensity probe, then the two-microphone intensity probe can be calibrated by fitting an intensity coupler attached to the pistonphone. See Chapter 51. The coupler normally consists of two chambers (upper and lower) connected by a coupling element. When the pistonphone is connected to the coupler, a phase difference is created between the two sound pressures generated in the upper and lower chambers. The sound pressure amplitudes are the same, however, in both chambers. Thus the propagation of a plane progressive sound wave in a free field is simulated. If one microphone of the intensity pair is fitted to the upper chamber and the other is fitted to the lower chamber, then the simulated sound wave produced by the sound in the two chambers can be used for the calibration of the intensity probe for the measurement of both sound intensity and particle velocity. The

intensity coupler and pistonphone can also be used for the sound pressure sensitivity calibration of the two microphones. For this measurement, the two microphones are connected to the upper chamber of the coupler. They are then automatically exposed to the same sound pressure, and the amplitude and phase difference between the two microphones can be measured and checked to see that it is within acceptable limits. If a sound source, which can generate broadband sound, is attached to the coupler, then the pressure residual-intensity index spectrum can be measured as well. This index is used to determine the accuracy of the sound intensity measurements made with the probe. See Chapters 45, 51, and 86.

5 VIBRATION MEASUREMENTS

A vibration sensor is a device that converts some property of the vibration of a structure into an electrical signal. While a vibration generator works on the opposite principle of converting an electrical signal into a mechanical vibration. Both vibration sensors and generators may be termed transducers, since they convert one physical variable into another. (See Chapter 37.)

Vibration sensors can be made to work using several different principles and to measure surface displacement, velocity, acceleration, and strain. They may be arbitrarily designated as contacting or noncontacting devices. Contacting sensors are often convenient to use since they can measure vibration at a specific location on a structure. They do have the disadvantage, however, that they can change the vibration of the structure by adding mass and damping. This is particularly a problem if the structure is lightweight.

There are three quantities of most interest in vibration studies.¹ These are *displacement*, *velocity*, and *acceleration*. A fourth quantity, *strain*, is also frequently measured. In the early 1900s, most vibration measurements were made using *mechanical or optical devices*. Such devices are still used satisfactorily for low-frequency measurements (a few hertz). With the advent of electronics in the 1920s, transducers that converted mechanical into electrical signals were developed. Before about 1960, displacement and particularly velocity-sensitive transducers were utilized, especially when higher frequency measurements were needed. However, since that time acceleration-sensitive transducers (accelerometers) have become preferred. The reason for this is mainly because excellent lightweight accelerometers were developed to measure very high frequency vibrations (5000 Hz or more) in aircraft and spacecraft. Most velocity-sensitive transducers have an upper limiting frequency of about 1000 Hz, while piezoelectric accelerometers can be made to have an upper limiting frequency of 40,000 Hz or more.¹

For many measurements it is unimportant whether displacement, velocity, or acceleration is measured. For simple harmonic motion, the amplitudes of these three quantities are simply related to each other by multiplying or dividing by the angular frequency ω

Figure 13 Idealized diagram of vibration transducer.

(see Chapters 1 and 43). Even if the vibration is random in nature, if frequency filtration is used, this principle can still be applied. Alternatively, the conversion from acceleration to velocity and displacement may be made by using electronic integration.

5.1 Principle of Seismic Mass Transducers

Modern-day piezoelectric accelerometers and some of the earlier displacement transducers¹⁵ work on the same principle: A seismic mass m is supported on a spring of stiffness k and the whole is enclosed in a case (Fig. 13). The damping constant R in most applications is small, and it is neglected for simplicity in the following analysis (although it could easily be included).

If the vibrating member (test piece) is undergoing a time-dependent displacement, $y_2(t)$, and the mass experiences a time-dependent displacement, $y_1(t)$, then considering the forces acting on the mass m ,

$$k(y_2 - y_1) = m\ddot{y}_1 \quad (3)$$

The situation is identical to that studied in Section 4.1C of Chapter 1, except that there is no external force applied to the mass, and instead the test piece receives a displacement input, $y_2(t)$.

The easiest variable to measure is the relative displacement $y_2 - y_1$. We will assume the test piece experiences simple harmonic motion:

$$y_2 = B e^{i\omega t} \quad (4)$$

and, consequently in steady-state conditions, the mass experiences simple harmonic motion, y_1 at the same angular frequency ω :

$$y_1 = A e^{i\omega t} \quad (5)$$

Note that A and B are written as complex quantities because y_1 and y_2 will not generally be in phase (see

Section 4.1C in Chapter 1). From Eqs. (3), (4), and (5) we obtain (noting that $i^2 = -1$)

$$k(\mathbf{B} - \mathbf{A})e^{i\omega t} = -m\omega^2 \mathbf{A}e^{i\omega t} \quad (6)$$

$$\mathbf{B} - \mathbf{A} = -(m\omega^2/k)\mathbf{A} \quad (7)$$

Rearranging Eq. (7) gives

$$\mathbf{A} = -\left(\frac{k}{m\omega^2 - k}\right)\mathbf{B} \quad (8)$$

and substituting Eq. (8) into Eq. (7) gives

$$\mathbf{B} - \mathbf{A} = \frac{m\omega^2}{m\omega^2 - k}\mathbf{B} \quad (9)$$

It is easy to see how this result can be used to design displacement, velocity, or acceleration transducers.

5.1.1 Seismic Mass Displacement and Velocity Transducers Seismic mass displacement and velocity transducers were widely used until the 1950s. They required a large seismic mass and a soft spring (between about 0.5 and 3 Hz) and were operated well above the system's natural frequency to obtain a flat frequency response curve. They were heavy and only suitable for use on heavy machinery.¹⁶ The soft spring gave a low resonance frequency between about 0.5 and 3 Hz, but the upper frequency limit was normally about 100 Hz due to limitations in the mechanical linkages used to measure the motion of the mass relative to the system's case. There are now several other displacement and velocity transducers available that do not suffer from this very limited frequency range. For example, the laser Doppler system can be used to measure dynamic displacement and velocity with a very high degree of precision.

5.1.2 Seismic Mass Acceleration Transducers

To measure acceleration conveniently with the seismic mass, the system shown in Fig. 13 must be used as follows. The ratio of relative displacement amplitude $|\mathbf{B} - \mathbf{A}|$ to test piece acceleration amplitude $\omega^2|\mathbf{B}|$ is from Eq. (9)

$$\frac{|\mathbf{B} - \mathbf{A}|}{\omega^2|\mathbf{B}|} = \frac{1}{|\omega^2 - \omega_n^2|} = \frac{1/\omega_n^2}{|1 - (\omega^2/\omega_n^2)|} \quad (10)$$

Except for the constant $(1/\omega_n^2)$ in the numerator, the right-hand side of Eq. (10) is identical to that of Eq. (19) in Chapter 1 with $\delta = 0$. If we had included damping in our model, the result would have again been identical to Eq. (19) in Chapter 1, except for the constant. Thus, we can make use of the results of Fig. 9 in Chapter 1. This figure shows that we should like to operate the instrument in the stiffness-controlled region, where $\omega/\omega_n \ll 1$.

Again this is obvious from Eq. (10), since, if $\omega/\omega_n \ll 1$, the right-hand side becomes a constant (equal to $1/\omega_n^2$). To obtain a flat frequency response over a wide frequency range, ω_n should be made large. But note that in this case the sensitivity decreases, since it is approximately proportional to $1/\omega_n^2$. To obtain a large value of the frequency ω_n , it is necessary to use a very stiff spring and a small mass, which is opposite to what is needed for seismic mass displacement and velocity transducers discussed above.¹

It is possible to measure the relative displacement by attaching a strain gauge to the spring and calibrating the instrument by the change in resistance produced. This is the principle of the *strain gauge* accelerometer, which is normally used with a Wheatstone bridge. Such accelerometers will usually be found to have an upper frequency limit of about 1000 or 2000 Hz. Provided that the accelerometer is dc coupled, it is easy to calibrate the accelerometer by inverting it. If the strain gauge accelerometer is placed horizontally, there is no signal; placed vertically in one direction it gives a constant resistance change equivalent to +1 g and placed in the opposite vertical position the change is equivalent to -1 g. If the accelerometer is alternating current (ac) coupled, such calibration is not possible. However, the most commonly used type of accelerometer is now the *piezoelectric accelerometer*.^{17,18}

5.2 Piezoelectric Accelerometers

The piezoelectric accelerometer is a seismic mass type of accelerometer that works on the principle described above. The main types include the following: compression, delta shear, planar shear, theta shear, annular shear, and ortho shear. These are all designed to accentuate certain advantages that are useful in different environmental conditions and are described in more detail in Chapter 37 and Section 12 of Chapter 43. As already discussed, the heavier accelerometers have the greatest sensitivity but the lowest resonance frequency and vice versa.

Several characteristics of piezoelectric accelerometers need to be considered. The piezoelectric accelerometer produces a charge after deformation. After the signal is passed through a charge converter (incorporated in modern piezoelectric accelerometers), it can be considered as a voltage source. Hence, the sensitivity is given in mV/ms^{-2} . Besides being sensitive to acceleration in the longitudinal axis, the accelerometer is also slightly sensitive to vibration in the transverse axis due to irregularities in construction and alignment of the piezoelectric disks. See Fig. 14. Good accelerometers should have a *lateral sensitivity* less than 5% of the longitudinal (or main axis) sensitivity. The transverse sensitivity will vary in the base plane having maximum and minimum values in certain directions. The sensitivity of an accelerometer will be somewhat temperature dependent (one should always consult the manufacturer's instructions), however, provided the maximum (Curie point) temperature is not exceeded, the piezoelectric material will not be damaged and will retain its properties.

Figure 14 Transverse and longitudinal sensitivity of accelerometer.

Piezoelectric accelerometers produce some output signal when subjected to acoustical signals or base strains. Normally the *acoustical sensitivity* is low (producing a false response output of less than 1 g for a sound pressure level input of 160 dB). As the test object vibrates, it will induce strain in the accelerometer base with a consequent output signal. Most accelerometer bases are made thick and rigid to reduce this effect.

As was discussed above (also see Chapter 37) all accelerometers exhibit a fundamental resonance frequency. The *frequency range* of an accelerometer is usually assumed to be bounded by an upper frequency limit of one third of the resonance frequency for less than 1-dB error or one fifth the resonance frequency for less than 0.5-dB error. This assumes that the accelerometer design has low damping. The upper frequency limit is extended in some accelerometer designs by using high damping. Today TEDS accelerometers are also available with built-in amplitude response information, so that the upper frequency limit is increased by about 50% to about one half of the resonance frequency.

The lower limiting frequency depends on the type of preamplifier used to follow the accelerometer. Two types may be used and are commercially available. If the preamplifier is designed so that the output voltage is proportional to the input voltage, it is called a voltage amplifier. If the output voltage is proportional to the input charge, it is called a charge amplifier. When a voltage amplifier is used, the accelerometer output voltage is very sensitive to cable capacitance. This is because typically the capacitance of a piezoelectric accelerometer is several hundred

picofarads (usually between 100 and 1000 pF). This is somewhere between the very low capacitance of a condenser microphone and the higher capacitance of a piezoelectric microphone (see Sections 4.1.1 and 4.1.3). When a charge amplifier is used, the output voltage is not sensitive to changes in cable length. Broch¹⁹ describes the reasons for this in some detail. If a voltage amplifier is used, the lower limiting frequency (3-dB down point) is given by

$$f_l = \frac{1}{2\pi RC} \quad (11)$$

where R is the input resistance of the voltage preamplifier and C is the effective circuit capacitance:

$$C = \frac{(C_A + C_L)C_C}{C_A + C_L + C_C} \quad (12)$$

where C_A , C_L , and C_C are the accelerometer, cable, and preamplifier capacitances, respectively.

The dynamic range of the piezoelectric accelerometer is determined by the lower limiting frequency set by electrical noise in the system and the upper limiting frequency governed by the preloading of the accelerometer and the mechanical strength of the piezoelectric element. Smaller accelerometers usually have a higher upper limit. (See Chapter 37.) It should also be noted that accelerometers have a main direction of sensitivity. See Fig. 14.

5.3 Measurement Difficulties

It should be noted that poor *mounting techniques* can have a marked effect on the frequency response above 2000 or 3000 Hz. Below this frequency, the mounting technique is not important as long as the accelerometer is fixed directly onto the specimen. The best technique is to attach the accelerometer to the specimen with a threaded steel stud. When this mounting method cannot be used, cement is also acceptable, and wax can be used with small to medium size accelerometers (up to 20 to 30 g).¹⁷ At low frequencies, magnets may be used. *Ground loops* must be avoided, in particular, when low acceleration levels are measured. With higher acceleration levels, ground loops can also cause problems. Measurement errors of 50% or more may be caused by ground loops with acceleration amplitudes of 100 m/s² or more. In such cases the accelerometer should be electrically isolated from the specimen and attached with a nonconducting stud or cemented to a mica washer, which is in turn cemented to the specimen. Cable “whip” can produce electrical noise, and cables should be attached to the specimen as shown in Fig. 15.

In the case of the measurement of high-frequency vibration of thin metal plates, considerable care should be taken when using an accelerometer because of the *mass loading* effect. Well below its resonance frequency, the accelerometer can be assumed to act as a pure mass. The velocity of the test piece u_0

Figure 15 Mounting of an accelerometer to reduce cable whip noise.

can be assumed reduced to u_1 by the addition of the accelerometer²⁰

$$\frac{u_1}{u_0} = \frac{Z}{Z + i\omega m} \quad (13)$$

where Z = mechanical impedance of test piece at the attachment point, ω = angular frequency, and m is the accelerometer mass.

The input point impedance for a metal plate can be assumed to be

$$Z = \frac{4}{\sqrt{3}} \rho c_L h^2 \quad (14)$$

where ρ = plate density, c_L = longitudinal wave speed in plate, and h = plate thickness.

Substituting Eq. (14) in Eq. (13) and assuming $|Z| = |i\omega m|$, which gives a 3-dB reduction in velocity amplitude (from Eq. 13), gives the frequency f_{3dB} at which the 3-dB reduction occurs as

$$f_{3dB} = \frac{2\rho c_L h^2}{\sqrt{3}\pi m} \quad (15)$$

Equation (15) is plotted in Fig. 16. This figure suggests that even lightweight accelerometers will “load” thin metal plates (e.g., a 10-g accelerometer will mass “load” a 3.2-mm ($\frac{1}{8}$ -in.) aluminum plate at frequencies above about 4000 Hz).

To overcome such mass loading problems, various types of noncontacting gauges have been produced and still are widely used. Particular examples of where noncontacting gauges are invaluable are in the study of the vibration of thin sandwich composite panels and of loudspeaker cones. Examples of noncontacting gauges are given in Chapter 37.

5.4 Calibration, Metrology, and Traceability of Shock and Vibration Transducers

Vibration measurements of acceleration, velocity, and displacement can be classified in two main ways: (1) relative measurements made between two points with systems such as laser Doppler interferometers and (2) absolute measurements made with seismic mass transducers (mainly accelerometers). The calibration of transducers used for both types of measurement is described in detail in Chapter 52. Chapter 52 also describes the traceability of vibration measurements and Chapter 53 describes the traceability of shock and

vibration measurements to national and international standards in more detail. In many ways the traceability requirements and calibration concerns for shock and vibration transducers are similar to those of microphones.

6 SIGNAL ANALYSIS, DATA PROCESSING, AND SPECIALIZED NOISE AND VIBRATION MEASUREMENTS

6.1 Signal Analysis and Data Processing

Sound and vibration signals produced by transducers are not normally in a suitable form for the study of noise and vibration problems. Frequency analysis is the most common approach used in the solution of such problems. This is because the human ear acts in many ways like a frequency analyzer (see Chapter 67) and also because frequency analysis can often be used to reveal information that can be related to the operation of machines, in particular rotating machinery and to the properties and the behavior of structures (see Chapter 68). Until the late 1970s, frequency analysis mostly was carried out with dedicated instruments that incorporated analog filters. Since that time, with the advent of the fast Fourier transform (FFT) algorithm, frequency analysis has been increasingly carried out using digital computers, either as part of a dedicated instrument or after appropriate conversion of the analog signal to digital form (known as A/D conversion). The analog signal is converted into a series of discrete values (also known as a time series). Dual and multichannel analyzers are also in common use for the parallel analysis of the signals from several transducers.

Besides carrying out frequency analysis of signals, analyzers have been made to calculate various other functions including cross-spectra, coherence between signals, and the like. Chapter 40 provides detailed explanations for the working of analyzers. Chapter 41 explains how measured noise and vibration data can be acquired, processed, shared, and stored using the power of modern digital computer systems. Chapter 42 deals with signal processing. This chapter summarizes the analog-to-digital conversion process, digital data storage and retrieval, basic computations used in noise and vibration data analysis, and errors associated with the various calculations. Important considerations in signal processing include sampling rate, sampling interval, resolution, and data format. The analog data must be sampled so that at least two sample values per cycle of the highest frequency of interest in the analog signal are obtained. The format of the data is also important, and it must be ensured that the data produced are in a form that they can be read directly by any computer program written in a common language such as C or FORTRAN.

6.2 Sound Level Meters and Dosimeters

The sound level meter (SLM) is an instrument designed to measure sound pressure over a frequency range and a sound pressure level range similar to the human ear. The basic SLM consists of a microphone,

amplifier, frequency weighting circuit(s), detector averaging circuit, and an analog or digital read-out device.²¹⁻²⁵ Miniaturization of electrical circuits and components has allowed small lightweight SLMs to be built, which possess considerable sophistication and capabilities. Also standards for SLMs written by successive national and international standards committees have resulted in different requirements and additional changes in SLM design and manufacture so that there is a wide variety of SLMs in use. There are four main types of SLM: 0, 1, 2, and 3. Type 0 meters are the most accurate and type 3

the least. The tolerances for the different types are specified in these standards. The different SLM types are generally used for precision, laboratory, field, and survey measurements. Dosimeters are similar in design to SLMs, except that the time constant, threshold, and exponent circuits are omitted.^{15,26} Dosimeters are worn on the person and are normally designed to measure the so-called noise dose, which is a percentage of a criterion exposure, where exposure is measured in pascal-squared hours. The noise dose calculated depends on the exchange rate used. In the United States, the Occupational Safety and Health

Figure 16 Effect of mass loading of an accelerometer on the vibration of a metal plate²⁰.

Administration (OSHA) requires a 5-dB exchange rate while the National Institute for Occupational Safety and Health (NIOSH) and most other countries use the 3-dB (equal energy) exchange rate. Chapter 38 reviews the main aspects of SLM design and also briefly describes dosimeter design. Chapter 39 reviews dosimeters in more detail.

6.3 Noise and Vibration Measurements

Chapter 43 deals with basic noise and vibration measurements. The chapter describes proper measurement techniques, measurement uncertainties, and repeatability of measurements. Not only are routine noise and vibration measurements described, but also measurement procedures specifically designed to measure reverberation time, vehicle passby noise, airport noise monitoring, aircraft takeoff and landing noise, and measurements of the sound absorption coefficient and acoustic impedance of materials with the impedance tube technique. An example of the use of the impedance tube to measure the sound-absorbing properties of porous asphalt road surfaces is given in this chapter. Other books have useful chapters on noise measurements, such as Ref. 28.

6.4 Sound Power and Sound Intensity

Measurements of the sound power of machines are frequently needed. The European Union requires some machines to be provided with labels giving their sound power output. From knowledge of the sound power level, the sound pressure level can be calculated at a certain distance from a machine, either outside in free space or in a building, provided certain environmental conditions are known. Chapter 44 describes several methods that can be used and that have been standardized both nationally and internationally. Also measurement surfaces including the spherical and box surfaces are described. Reverberation time and comparison methods of measuring sound power are also reviewed in Chapter 44.

Sound intensity measurements described in Chapter 45 provide another method of determining the sound power output of sources, and this approach is particularly useful when the machine cannot be moved into a special facility such as an anechoic room or a reverberation room. In addition, the sound intensity approach can still be used to determine the sound power of a sound source when there is a hostile background noise present. Provided that the background noise is steady, good estimates of the sound power of a source can be made, even if the background noise level is very high. In such situations, the approaches described to obtain the sound power of sources in Chapter 44 normally fail.

Chapter 46 provides further in-depth discussion on data analysis with an emphasis on the use of such analysis to solve noise and vibration problems. Also some basic concepts including types of signals, probability distribution, and probability density are described. The chapter also describes techniques such as zoom analysis, practical FFT analysis, spectrum

averaging, and spectral analysis using filters, time-domain analysis, time synchronous averaging, and analysis of cyclo-stationary signals. Cyclo-stationary signal analysis has recently become the subject of increasing interest since it is now evident that many machine vibration signals are not purely periodic, since their vibrations possess amplitude modulations as well. This chapter explains how some of the data analysis techniques can be applied to vibration caused by worn roller bearings and diesel engine noise.

6.5 Modal Analysis

Modal analysis can be used to provide information concerning the natural frequencies, modal damping factors, and mode shapes of structures and machinery. This information can be obtained either from mathematical analysis of a structure's dynamic response derived from a set of equations and knowledge of its mass and stiffness distributions or from experimental measurements of the structure's response to excitation. Experimental modal analysis (often simply known as modal testing) is discussed in detail in Chapter 47. As explained in this chapter, however, modal testing cannot be divorced from mathematical models of the structure's dynamical behavior and the objective of modal testing in reality is an attempt to construct or validate a mathematical model of this behavior. Unfortunately, such mathematical models obtained through modal testing can never be quite complete because, in practice, the amount of experimental data obtained is inevitably limited. Usually, the mathematical model to be validated is a finite element model of the structure. Modal analysis is used for several main purposes. These include (a) monitoring the dynamic properties of a structure or machine to obtain early indications of structural deterioration or impending failure (often known as structural or machinery health monitoring), (b) modification of a structure's mass or stiffness distributions so as to change natural frequencies to avoid high-amplitude resonant vibration, the resulting structural fatigue and the possibility of failure, and (c) troubleshooting—the display of animated modes of vibration of the structure so that the dynamic behavior of certain critical areas of the structure can be understood, thus making possible practical solutions to vibration problems.

6.6 Condition Monitoring

Condition monitoring is discussed in Chapter 48. Such monitoring of machinery may give sufficient advance warning of wear and possible imminent breakdown and failure so that replacement parts can be obtained in time to avoid costly machine downtime and/or loss of production. Costs savings can be considerable, for instance, in the case of downtime of a city electrical power plant, where unexpected downtime losses can exceed several million U.S. dollars each day. The savings in avoiding unnecessary downtime costs often vastly exceed the costs of replacement machine parts. In cases such as aircraft power plants, predictive maintenance can even prevent the possibility

of catastrophic failure of the compressor blades and other components of the engines.

Chapter 48 describes two main approaches to condition monitoring: (1) monitoring the relative displacement of a rotating machine shaft or bearing with a proximity probe and (2) monitoring the vibration of the cover of a machine. Proximity probes are normally built into machines during manufacture; while, on the other hand, accelerometers can be placed on the cover of a machine at any time during service to monitor its vibration. Proximity probes are usually used to monitor changes in absolute shaft displacement and to measure so-called shaft orbits. Chapter 57 in the *Handbook of Acoustics*³ also contains useful information concerning monitoring changes in shaft motion with the use of proximity probes. Chapter 48 is mainly concerned with vibration measurements of machine casings made with accelerometers. If a machine is monitored in its original new condition, measurements made later may reveal changes indicating wear and the possibility of failure. Faults related to the frequency of the shaft speed include: misalignment, imbalance, and cracks in the drive shaft. It is usually difficult to distinguish between these faults. Useful information is given in Chapter 48 about the changes in the vibration signature, which manifest themselves with electrical machines, gears, bearings, and reciprocating machinery such as internal combustion engines, pumps, compressors, and the like.

6.7 Advanced Noise and Vibration Analysis and Measurement Techniques

Wavelets are starting to become of practical use in the solution of noise and vibration problems, machinery diagnostics, and health monitoring. Wavelet analysis is concerned with the decomposition of time signals into short waves or *wavelets*. Any waveform may be used for such decomposition provided that it is localized at a particular time (or position). Chapter 49 provides an in-depth discussion of the basics of wavelet analysis of signals, and in this chapter time is taken as the independent variable, although, in practice, any physical variable can be used. The Fourier coefficients of a signal are obtained by averaging over the full length of the signal, and the result is that no information is provided about how the frequency content of the signal may be changing with time.

In principle, the short-time Fourier transform (STFT) does provide this needed frequency time variation information, by dividing the time record of the signal into sections, each of which is analyzed separately. The frequency coefficients of the signal computed by the STFT depend on the length and time (or position) of the short record that the calculation process assumes is one period of an infinitely long periodic signal (see Chapters 40, 42, and 46). The difficulty remains, however, that infinitely long harmonic functions are being used to decompose a transient signal. Wavelets are short functions that avoid this difficulty. A set of wavelet functions is used as the basis for the decomposition of transient time-history signal records.

Near-field acoustical holography is a technique that can be used to reconstruct the frequency spectrum of any sound field descriptor (i.e., sound pressure, particle velocity, and sound intensity) at any location in space, normal surface velocity/displacement, directivity patterns, and the total sound power of a source. This is achieved by making a sound pressure on a planar surface located near to the source's surface with either a scanning microphone (or hydrophone) or an array of microphones. If a scanning microphone is used, it should be robot controlled. The procedure essentially creates a near-field hologram and relies on the measurement of the phase relationship between all of the sensor elements in the array that is used. If a scanning microphone is used instead, then the phase relationship is obtained by comparisons with a reference signal, which is kept stationary throughout the measurement. The approach can be used both with sources that are random in nature (such as fluid flow or boundary layer noise sources) and with deterministic sources (such as those containing pure tones like noise from a propeller). Although the approach is not simple, it eliminates the need for costly facilities and relies on the use of software instead, some of which is becoming commercially available. Chapter 50 describes the theory behind this approach and also describes its use in practice to determine the in-flight sound pressure, normal surface velocity, and sound intensity on the interior fuselage surface and the floor of a passenger commuter aircraft.

CHAPTER 36

ACOUSTICAL TRANSDUCER PRINCIPLES AND TYPES OF MICROPHONES

Gunnar Rasmussen and Per Rasmussen
G.R.A.S. Sound & Vibration
Holte, Denmark

1 INTRODUCTION

A microphone can be defined as a device that converts some property of an acoustic field into an electrical signal. The property of the sound field most often measured is the sound pressure, but other properties like pressure gradient or particle velocity may also be measured. The microphones may be broadly divided into three classes, according to their applications:

- *Communication microphones:* These are microphones for a wide range of applications, such as telephones, mobile telephones, dictaphones, walkie talkies, toys, hearing aids, and computer peripherals. The main factors for these applications are cost, size, and ruggedness.
- *Studio microphone:* A broad range of microphones for recording music and speech, such as on-stage performances and public address (PA) systems, and television. Some of the main factors for this class of microphones are performance, reliability, and design (appearance).
- *Measurement microphones:* For laboratory measurements, environmental measurements, type approval, and product labeling measurements. The main factors are precision, long-term stability, and calibration.

For each of the applications, the microphones may be developed to meet specifications for dynamic range, frequency range, size, and frequency response.

2 TYPES OF MICROPHONES

Different types of microphones may be divided according to the conversion principle used for converting the sound-field-related property to an electrical signal. In 1877, Thomas A. Edison invented the carbon lamp-black button microphone. This was one of the first practical microphones of the variable-resistor types. These microphones employed a diaphragm to convert the sound pressure signal into a mechanical force acting on carbon granulate. The force acting on the carbon granulate would change the electrical resistance of carbon and thereby modulate a bias current. This would provide a low output impedance signal that could be transmitted over considerable distances without amplification and was therefore quickly adopted for telephone use. The ability to be used without amplifying devices far outweighed its many disadvantages: poor temperature stability, sensitivity to humidity, and

problems with long-term as well as short-term stability and high noise floor. With the wide availability of amplifying devices and very high impedance input FETs (field-effect transistors), the carbon microphone is very seldom used today and will not be discussed further.

3 CONDENSER MICROPHONES

The most widely used microphone type today is the condenser-type microphone. This was invented in 1917 by E.C. Wentz and has since been developed further. The condenser-type microphone is available in the so-called externally polarized versions and in the prepolarized version, sometimes also called electret microphones. As the basic function of these types is almost the same, these will be handled together.

In a condenser microphone, a metallic or conducting diaphragm is placed close to and parallel with a backplate (Fig. 1), so that the diaphragm and the backplate form a capacitor. The capacity C_m of this capacitor is given by

$$C_m = \frac{\epsilon_0 \pi b^2}{h} \quad (1)$$

where ϵ_0 is the dielectric constant for air, b is the radius of the backplate, and h is the equilibrium distance between the backplate and the diaphragm. This capacitor is charged by a voltage source V_c through a large series resistor R_c so that the charge Q_c on the microphone becomes

$$Q_c = C_m V_c = V_c \frac{\epsilon_0 \pi b^2}{h} \quad (2)$$

Figure 1 Condenser microphone principle.

If the pressure outside the microphone is different from the pressure inside the microphone, the diaphragm will be displaced from its equilibrium position. If the diaphragm is displaced by an amount x , this will, according to Eq. (1), cause a change in the microphone capacity:

$$C_{m,\Delta} = \frac{\epsilon_0 \pi b^2}{h+x} \quad (3)$$

The large series resistor R_c and a high input impedance preamplifier ensures that the charge Q_c in Eq. (2) is kept constant. The change in capacity will therefore result in a change in the voltage V_{out} across the microphone capacitor:

$$Q_c = C_m V_c = C_{m,\Delta} V_{out} = V_{out} \frac{\epsilon_0 \pi b^2}{h+x} \quad (4)$$

Combining Eqs. (2) and (4) gives

$$V_{out} = V_c \frac{h+x}{h} \quad (5)$$

A pressure difference p between the inside and the outside of the microphone will give a resulting diaphragm force F given by

$$F = pA \quad (6)$$

where A is the effective diaphragm area. If Z_m is the mechanical impedance of the diaphragm, the resulting displacement of the diaphragm (Fig. 2) will be

$$x = \frac{F}{j\omega Z_m} = \frac{A}{j\omega Z_m} p \quad (7)$$

and the output signal from the microphone will be

$$V_{out} = V_c \frac{h + p(A/j\omega Z_m)}{h} \quad (8)$$

Figure 2 Condenser microphone diaphragm deflection.

This equation shows that, for an overpressure outside the microphone, where the diaphragm is deflected toward the backplate (corresponding to a negative x), the output signal will go down.

In general, the mechanical impedance of the diaphragm can be expressed as

$$Z_m = j\omega m_m + r_m + \frac{1}{j\omega c_m} \quad (9)$$

where m_m is the diaphragm mass, r_m is the damping in the microphone, and c_m is the stiffness of the diaphragm. It can be seen from Eq. (8) that in order to obtain a flat frequency response, the mechanical impedance of the diaphragm must be controlled by the diaphragm stiffness, and the contributions from mass and damping must be negligible:

$$Z_m \approx \frac{1}{j\omega c_m} \quad (10)$$

and if this is substituted in Eq. (8), the microphone output as a function of the input pressure is given by

$$V_{out} = V_c \frac{h + pAc_m}{h} \quad (11)$$

In practice, the microphone capacity is loaded by stray capacitance and the input impedance of the preamplifier, and this will lead to nonideal situations with limitations in performance and frequency range.

The prepolarized microphone, or electret-type microphone, is similar to the above-mentioned externally polarized microphone; only the polarization voltage is not established by an external voltage source. The polarization voltage is established by injecting an electrical charge into a thin layer of PTFE (polytetrafluoroethylene) or similar material, usually on the microphone backplate. Due to the high resistance of PTFE, the electrical charge decays only very slowly (decay rates from years to hundreds of years, depending on temperature).

4 ELECTRODYNAMIC MICROPHONES

The electrodynamic microphone is, in principle, similar in build to an electrodynamic loudspeaker. However, instead of converting an electrical signal to sound, the sound pressure is converted to an electrical signal. The microphone (Fig. 3) consists of a stiff diaphragm loosely supported so that it can move freely. A coil is attached to the diaphragm, and the coil can be moved in a strong magnetic field caused by a permanent magnet.

A pressure difference p between the inside and the outside of the microphone will give a resulting diaphragm force F given by

$$F = pA \quad (12)$$

Figure 3 Dynamic microphone principle.

where A is the effective diaphragm area. If Z_m is the mechanical impedance of the diaphragm system, the resulting velocity v of the diaphragm and coil will be

$$v = \frac{pA}{Z_m} \quad (13)$$

As the coil is moving in the magnetic field B , this gives an output voltage V_{out} of

$$V_{\text{out}} = \frac{BlA}{Z_m} p \quad (14)$$

where l is the length of the wire in the coil.

Again, the diaphragm impedance is given as

$$Z_m = j\omega m_m + r_m + \frac{1}{j\omega c_m} \quad (15)$$

It can be seen from Eq. (14) that in order to obtain a flat frequency response, the mechanical impedance of the diaphragm must be controlled by the damping and the contributions from mass and stiffness must be negligible:

$$Z_m \approx r_m \quad (16)$$

and if this is substituted in Eq. (14), the microphone output as a function of the input pressure is given by

$$V_{\text{out}} = \frac{BlA}{r_m} p \quad (17)$$

so that in order for the microphone to give a flat frequency response, the diaphragm movement should be controlled by the damping.

5 PIEZOELECTRIC MICROPHONES

A wide variety of crystals and crystalline substances exhibit piezoelectric effects when mechanically deformed. This phenomenon is utilized in many types

Figure 4 Piezoelectric microphone principle.

of transducers, including piezoelectric microphones and pressure transducers.

The piezoelectric microphone consists of a stiff diaphragm that is coupled to a piezoelectric crystal or ceramic substrate, as shown in Fig. 4. The output signal from the piezoelectric element is proportional to the mechanical displacement x of the element:

$$V_{\text{out}} = C_p x \quad (18)$$

where C_p is a constant for the piezoelectric element. A pressure difference p between the inside and the outside of the microphone will give a resulting diaphragm force F given by

$$F = pA \quad (19)$$

where A is the effective diaphragm area. If Z_m is the mechanical impedance of the piezoelectric element at the contact point with the diaphragm, the resulting displacement of the piezoelectric element will be

$$x = \frac{F}{j\omega Z_m} = \frac{A}{j\omega Z_m} p \quad (20)$$

and the output signal from the microphone will be

$$V_{\text{out}} = C_p \frac{A}{j\omega Z_m} p \quad (21)$$

Again, the diaphragm impedance is given as

$$Z_m = j\omega m_m + r_m + \frac{1}{j\omega c_m} \quad (22)$$

It can be seen from Eq. (21) that in order to obtain a flat frequency response, the mechanical impedance of the diaphragm must be controlled by the diaphragm stiffness and the contributions that form the mass and damping must be negligible:

$$Z_m \approx \frac{1}{j\omega c_m} \quad (23)$$

and if this is substituted in Eq. (21), the microphone output as a function of the input pressure is given by

$$V_{\text{out}} = C_p A c_m p \quad (24)$$

6 MICROPHONE DIRECTIVITY

Sound pressure is a scalar quantity and as such does not have any directional properties or information. However, a sound field may have a propagation direction, that is, the sound waves propagate in a certain direction. Different microphones may have different responses as a function of the orientation of the microphone relative to the orientation of the sound field. This may be expressed as

$$R(f, \theta) = \frac{V(f, \theta)}{V(f, 0^\circ)} \quad (25)$$

where $V(f, \theta)$ is the output of the microphone as a function of frequency f for an angle θ between the microphone and the propagation direction of the sound field, and $V(f, 0^\circ)$ is the output of the microphone as a function of frequency f for an angle $\theta = 0^\circ$ between the microphone and the propagation direction of the sound field (0° incidence).

In general, microphones can be divided into directional microphones or omnidirectional microphones. Both types will eventually have a certain directionality, especially at higher frequencies where diffractions around the microphone start to change the acoustical field. While directional microphones are designed to obtain a certain directionality, omnidirectional microphones are designed to minimize directionality effects.

7 DIRECTIONAL MICROPHONES

Directionality microphones are designed so that both sides of the microphone diaphragm are exposed to the sound field, but with a delay in the sound signal from the front of the microphone to the back of the microphone.

For the microphone in a sound field (Fig. 5) the sound wave arrives first at the front of the microphone. Then the sound wave travels a distance l_1 to the back of the microphone. This distance depends on the size

Figure 5 Directional microphone.

(diameter) of the microphone and on the angle θ of the microphone relative to the propagation direction of the microphone:

$$l_1 = l_m \cos \theta \quad (26)$$

where l_m is a constant for the microphone depending on its size and geometry.

As the sound wave reaches the back of the microphone, it has to travel a further distance of l_2 , which is independent of the angle θ , but depends only on the design and geometry of the microphone. The total travel length l_t for the sound wave, therefore, becomes

$$l_t = l_1 + l_2 = l_m \cos \theta + l_2 \quad (27)$$

If the pressure of the incoming wave is p and the diaphragm area is S , the resulting force F on the diaphragm will be

$$\begin{aligned} F &= -dx \frac{\partial p}{\partial x} S = -l_t \frac{\partial p}{\partial x} S = -(l_m \cos \theta + l_2) \frac{\partial p}{\partial x} S \\ &= -(l_m \cos \theta + l_2) k p S \end{aligned} \quad (28)$$

Since the wave number k is proportional to the frequency f ,

$$k = \frac{2\pi f}{c} \quad (29)$$

the force F acting on the diaphragm will be proportional to the frequency. And to obtain a flat frequency response, the diaphragm impedance has either to be designed so that the output of the microphone is inversely proportional to the diaphragm force or it has to be corrected for electrically afterwards.

The actual directivity is independent of the frequency as long as the dimensions l_m and l_2 are small compared to the wavelength. The directivity is given by Eqs. (25) and (28):

$$\begin{aligned} R(\theta) &= \frac{-(l_m \cos \theta + l_2) k p S}{-(l_m + l_2) k p S} = \frac{l_m \cos \theta + l_2}{l_m + l_2} \\ &= \frac{(l_m/l_2) \cos \theta + 1}{(l_m/l_2) + 1} \end{aligned} \quad (30)$$

It can be seen that the directivity depends only on the ratio K :

$$K = \frac{l_m}{l_2} \quad (31)$$

Figure 6 shows some examples of the directivity plots for various ratios of K .

8 OMNIDIRECTIONAL MICROPHONE

As mentioned above, pressure is a scalar quantity and, as such, does not possess any directional information. Therefore, a pressure transducer is by definition an omnidirectional transducer.

Figure 6 Microphone directivity for different K factors: (a) $K = 0.5$, (b) $K = 1$, and (c) $K = 2$.

This is true at low frequencies, but at higher frequencies, where the dimensions of the transducer become comparable to the wavelength, diffraction around the microphone will change the response.

In connection with the measurement of sound pressure, three types of microphones are used. These are: free-field microphones, pressure microphones, and random-incidence microphones. They are constructed to have different frequency characteristics in order to comply with different requirements.

9 PRESSURE MICROPHONE

The pressure microphone is constructed to measure the actual sound pressure as it exists on the diaphragm. A typical application is the measurement of sound pressure in a closed coupler or the measurement of sound pressure at a boundary, such as a wall. In

this case, the microphone forms part of the wall and measures the sound pressure on the wall itself. The frequency response of this microphone should be flat over a wide-as-possible frequency range, taking into account that the sensitivity will decrease with increased frequency range. The acoustic damping in the air gap between the diaphragm and backplate is adjusted so that the frequency response is flat up to and a little beyond the resonant frequency.

10 FREE-FIELD MICROPHONE

The introduction of a microphone into a sound field will result in a pressure increase in front of the diaphragm (Fig. 7), depending on the wavelength. The free-field microphone is designed essentially to measure the sound pressure as it existed before the microphone was introduced into the sound field. At

Figure 7 Pressure increase in front of microphone due to diffraction.

higher frequencies, the presence of the microphone in the sound field will change the sound pressure. Generally, the sound pressure around the microphone cartridge will increase due to reflections and diffraction. The free-field microphone is designed so that its frequency characteristics compensate for this pressure increase. The resulting output of the free-field microphone is a signal proportional to the sound pressure as it existed before the microphone was introduced into the sound field.

The free-field microphone should always point toward the sound source (0° incidence) (Fig. 8a).

For a typical 0.5-in. microphone, the maximum pressure increase will occur at 26.9 kHz, where the wavelength of the sound coincides with the diameter of the microphone [$\lambda = (342 \text{ m/s})/(26.9 \text{ kHz}) \approx 12.7 \text{ mm} \approx 0.5 \text{ in.}$]. The microphone then must be designed so that its sensitivity decreases by an amount that compensates for increased acoustic pressure in front of the diaphragm. This is done by increasing the internal acoustic damping in the microphone cartridge in order to obtain the desired frequency response (Fig. 8b) (see Section 12).

The result is an output from the microphone that is proportional to the sound pressure as it existed before the microphone was introduced into the sound field (Fig. 8c). The curve in Fig. 8a is also called the free-field correction curve for the microphone and must be added to the pressure frequency response of the microphone cartridge to obtain the acoustical characteristic of the microphone in a free field.

11 RANDOM-INCIDENCE MICROPHONE

In principle, the free-field microphone needs to be pointed toward the sound source in conditions where sound waves travel essentially in one direction. In some cases, for example, when measuring in a reverberation room or other highly reflecting surroundings, sound waves will not have a well-defined propagation direction but will arrive at the microphone from

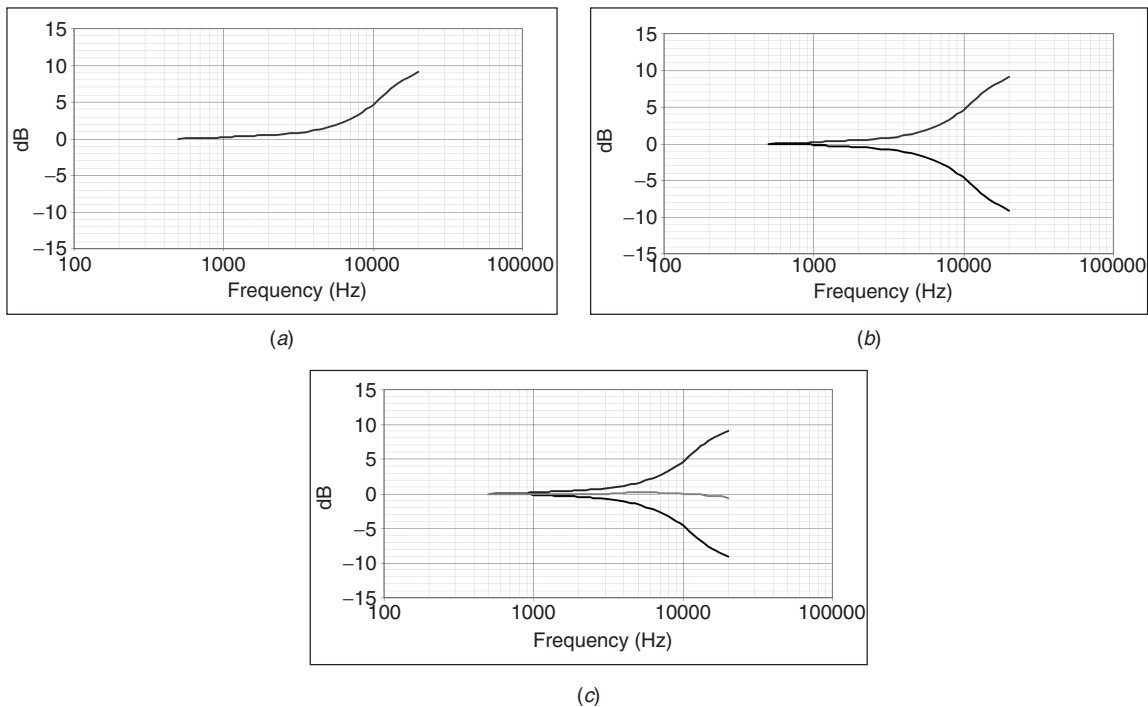

Figure 8 Frequency response of typical free field microphone: (a) Pressure increase in front of microphone due to diffraction. (b) Pressure response of microphone. (c) Resulting free-field response of microphone.

all directions simultaneously. The sound waves arriving at the microphone from the front will cause a pressure increase as described above for the free-field microphone, whereas sound waves arriving from the back of the microphone will cause a pressure decrease to a certain extent due to the shadowing effects of the microphone cartridge. The combined influence of the waves coming from different directions depends, therefore, on the distribution of sound waves from the different directions. For measurement microphones, a standard distribution has been defined, based on statistical considerations, resulting in a standardized random-incidence microphone.

12 MICROPHONE DESIGN PARAMETERS

The basic characteristics of a microphone are determined by factors such as size, diaphragm tension, distance between the diaphragm and the backplate, and the acoustic damping within the microphone. These factors will determine the frequency range of the microphone, its sensitivity, and its dynamic range. The sensitivity is described as the output voltage of the microphone for a given sound pressure excitation, and, in itself, is of little interest for the operation of the microphone, except for calibration purposes. However, the sensitivity of the microphone (together with the electrical impedance of its cartridge) also determines the lowest sound pressure level that can be measured with the microphone. The size of the microphone is the first parameter determining its sensitivity. Generally, the larger the diameter of the diaphragm, the more sensitive the microphone will be. There are, however, limits to how sensitive the microphone can be made simply by making it larger. The polarization voltage causes the diaphragm to be attracted, and deflected, toward the backplate. When the size of the microphone is increased, this deflection will also increase, and eventually the diaphragm will be deflected so much that it will actually touch the backplate. To avoid this, the distance between the diaphragm and the backplate can be increased or the polarization voltage can be lowered, in both cases leading to a decrease in sensitivity. The optimum practical size of a measurement microphone for use up to 20 kHz is very close to 0.5 inch (12.7 mm). In some special applications involving very low level measurements, 1-inch (25.4-mm) microphones may be required, but for the majority of applications, 0.5 inch or smaller is the better choice.

When the size of the microphone is decreased, the useful frequency range is increased. The frequency range obtainable is determined, in part, by the size of the microphone. At high frequencies, when the wavelength of sound waves becomes much smaller than the diameter of the diaphragm, the diaphragm will stop behaving like a rigid piston (the diaphragm is said to “break up”—not a destructive phenomenon). Different parts of the diaphragm will start to move with differing magnitude and phase, bringing about a change in the microphone’s frequency response. To avoid this, the upper limiting frequency is placed such that the sensitivity of the microphone drops off before

the diaphragm starts to break up. For a typical 0.5-inch microphone, the upper limiting frequency is placed in the range of 20 to 40 kHz, depending on diaphragm tension. If the diaphragm is tensioned, that is, made stiffer, its resonance frequency will be higher; on the other hand, the sensitivity of the microphone will be reduced because the diaphragm will deflect less for a given sound pressure level.

The frequency response of a microphone is determined by diaphragm tension, diaphragm mass, and the acoustic damping in the air gap between the diaphragm and backplate. This system can be represented by a simple mass–spring–damper system, as seen in Fig. 9. In this analogy, the mass represents the mass of the diaphragm, and the spring represents the tension in the diaphragm. Thus, if the diaphragm is tensioned to make it stiffer, the corresponding spring becomes stiffer. The damping element in the analogy represents the acoustic damping between the diaphragm and the backplate. This can be adjusted, for example, by drilling holes in the backplate, which will make it easier for the air to slip away from the air gap when the diaphragm is deflected, thereby decreasing damping.

This simple mechanical analogy of the microphone is a first-order mechanical system with a simple frequency response. At low frequencies (below resonant frequency), the response of the microphone is determined by the diaphragm tension (Fig. 10). If the diaphragm tension is increased, the output of the microphone will decrease, and if it is decreased, the output will increase. The tension and mass of the diaphragm determine the resonant frequency such that an increase in tension increases the resonant frequency, and an increase in mass decreases the resonant frequency. The response around the resonant frequency (Fig. 11) is determined by the acoustic damping, where an increase in damping will decrease the response. At higher frequencies, above the resonant frequency, the response of the microphone to sound pressure is determined by the mass of the diaphragm. The greater the mass of the diaphragm, the smaller will be the output signal from the microphone since the sound pressure has greater difficulty in moving the diaphragm.

Figure 9 Microphone equivalent system.

Figure 10 Microphone parameters.

Figure 11 Microphone resonance damping.

13 DYNAMIC RANGE

The dynamic range of a microphone is the range between the highest and the lowest sound pressures that can be handled by the microphone. The highest level is determined by the distance between the backplate and the diaphragm, usually on the order of $20\text{ }\mu\text{m}$ ($2 \times 10^{-5}\text{m}$). If the sound pressure is high enough, it will deflect the diaphragm so much that it will actually touch the backplate. In this situation, the microphone will become highly nonlinear. Thus, it is usual to limit the maximum deflection to about one-tenth of the distance between the backplate and the diaphragm. For a typical 0.5-inch measurement microphone, this will be around 140 dB (relative to $2 \times 10^{-5}\text{ Pa}$). As the sound pressure is decreased, diaphragm movement is also decreased proportionally. Thus, at a sound pressure level of 20 dB (relative

to $2 \times 10^{-5}\text{ Pa}$), the movement of the diaphragm is reduced by a factor of 10^{-6} (120 dB), giving a diaphragm movement of around $2 \times 10^{-12}\text{ m}$.

The lowest level of sound pressure is determined by the inherent noise generated in the microphone itself and the conversion factor from pressure to voltage in connection with the preamplifier. The inherent noise generated by the microphone is associated with the damping in a simple mechanical model.¹ In an electrical analogy of this mechanical model, the damping is present in the form of a resistor R_A , and the Johnson noise from this resistor, expressed as power spectral density (PSD), is given by the Nyquist equation:

$$\text{PSD} = p_{\text{rms}}^2 / \Delta f = 4k_B T R_A \quad (32)$$

where k_B is the Boltzmann constant and T is the absolute temperature. It can be seen that this causes a frequency-independent thermal noise contribution proportional to the damping.

The Johnson noise contribution will be present on the output terminal of the microphone and is superimposed on the signal generated by the sound pressure on the diaphragm. This signal is given by the sound pressure p_i on the diaphragm and the sensitivity S_m . The sensitivity, or electromechanical coupling coefficient, is the ratio between the sound pressure and resulting output voltage. The total output V_o from the

microphone is therefore given by

$$V_o = N_s + p_i S_m \quad (33)$$

where N_s is the thermal noise contribution. It can be seen that the lower limit can be extended downward either by increasing the sensitivity or by decreasing the damping.

CHAPTER 37

VIBRATION TRANSDUCER PRINCIPLES AND TYPES OF VIBRATION TRANSDUCERS

Colin H. Hansen
School of Mechanical Engineering
University of Adelaide
Adelaide, South Australia, Australia

1 INTRODUCTION

Vibration transducers are used widely in noise, shock, and vibration control. There are two main types of vibration transducers: (1) vibration sensors, which convert vibration to an electrical signal (voltage or charge), and (2) generators, which work on the principle of converting an electrical voltage or current to a mechanical vibration.

There are several important properties that must be considered in the design and selection of a vibration transducer. The *sensitivity* of a measurement transducer represents the smallest quantity that it can measure. The term can also refer to the effect of various environmental parameters such as temperature, magnetic fields, and the like on the transducer output. The *dynamic range* represents the ratio of the largest to smallest quantities that can be measured and is usually expressed in decibels, while the *frequency range* is the range of frequencies to which a measurement transducer is sensitive or an actuator can excite. The electrical quantity that defines the electrical input or output of a transducer in terms of the relationship between voltage and current is known as the *input/output impedance*.

There are a number of Internet sites where more detailed information on vibration transducers is available. Two useful sites are www.endevco.com and www.bk.dk. At the first site a handbook of dynamic measurement can be downloaded, and at the second a number of technical reviews are available that deal exclusively with vibration measurement. In addition to these sites, there are a number of useful handbooks that include vibration measurement information, including the one by Harris and Piersol.¹

2 VIBRATION SENSORS

Prior to discussing vibration sensors in detail, it is useful to point out the relationships between the acceleration, velocity, and displacement of a vibrating object. For single frequencies or narrow bands of noise, the displacement d , velocity v , and acceleration a are related by the frequency ω (rad/s), as $d/\omega^2 = v/\omega = a$. In terms of phase angle, velocity leads displacement by 90° and acceleration leads velocity by 90° . For narrow-band or broadband signals, velocity and displacement can also be derived from

acceleration measurements using electronic integrating circuits. On the other hand, deriving velocity and acceleration signals by differentiating displacement signals is generally not practical due primarily to the limited dynamic range of displacement transducers and secondarily to the cost of differentiating electronics.

2.1 Accelerometers

Vibratory motion is often sensed by using an accelerometer attached to the vibrating surface. These transducers, may be either piezoresistive or piezoelectric in nature.

Piezoelectric accelerometers consist of a small mass attached to a piezoelectric crystal. The inertia force due to acceleration of the mass causes stress in the crystal that in turn produces a voltage proportional to the stress (or acceleration of the mass). The mass may be mounted to produce either compressive/tensile stress or, alternatively, shear stress in the crystal. The latter arrangement allows a smaller (and lighter) accelerometer for the same sensitivity. It also results in less sensitivity to base strain and temperature.

Three piezoelectric accelerometer types are illustrated in Fig. 1a, 1b, and 1c and a schematic of the delta shear type is shown in Fig. 1d. All these figures are adapted from the Brüel and Kjær accelerometer handbook.² Piezoelectric accelerometers are by far the most commonly used.

Another type of piezoelectric accelerometer that is much less expensive is one made using piezoelectric polymer film (polyvinylidene fluoride, or PVDF) in place of the piezoelectric crystal. These accelerometers are used in mass production applications such as air bags in cars.

Piezoresistive accelerometers, which are a third type, rely on the measurement of resistance change in a piezoresistive element subjected to stress. The element is generally mounted on a beam, as in Fig. 2. They are less common than piezoelectric crystal accelerometers and generally less sensitive by an order of magnitude for the same size and frequency response. Also, they require a stable direct current (dc) power supply to excite the piezoresistive element (or elements). However, piezoresistive accelerometers are capable of measuring down to dc (or zero frequency), are easily calibrated at dc, and can be used effectively with low-impedance voltage amplifiers.

Figure 1 Piezoelectric accelerometer configurations: (a) planar shear type, (b) delta shear type, (c) compression type, and (d) schematic of delta shear type. M = seismic mass, P = piezoelectric element, R = clamping ring, and B = base. (Adapted from Brüel and Kjær.²)

When choosing an accelerometer, some compromise must always be made between weight and sensitivity. Small accelerometers are more convenient to use, can measure higher frequencies, and are less likely to affect the vibration characteristics of the structure by mass loading it. However, they have low sensitivity, which puts a lower limit on the acceleration amplitude that can be measured. Accelerometers range in weight from miniature 0.2 g for high-level vibration amplitude (up to a frequency of 18 kHz) on light-weight structures to 500 g for low-level vibration measurement on heavy structures (up to a frequency of 1 kHz). Thus, prior to choosing an accelerometer, it is necessary to know approximately the range of vibration amplitudes and frequencies to be expected as well as detailed accelerometer characteristics, including the effect of various amplifier types. The latter information should be readily available from the accelerometer manufacturer.

Accelerometers often have preamplifiers built into their casing so that their output can be fed into a standard voltage amplifier. When no in-built preamplifier exists, the signals are usually preconditioned by a charge amplifier before further amplification or connection to instrumentation such as a spectrum analyzer. Charge amplifiers act to virtually short circuit the accelerometer output and integrate the current running through this short circuit giving the resulting charge (coulomb = amperes \times seconds). This makes

them insensitive to cable capacitance (and thereby length) and to leakage resistance, which would modify the lower limiting frequency of a voltage amplifier. Charge amplifiers allow measurement of acceleration down to frequencies of 0.2 Hz, and they are insensitive to cable lengths up to 500 m. Many charge amplifiers also have the capability of integrating acceleration signals to produce signals proportional to velocity or displacement. Particularly at low frequencies, this facility should be used with care, as phase errors and high levels of electronic noise will be present, especially if double integration is used to obtain a displacement signal.

The minimum vibration level that can be measured by an accelerometer is dependent upon its sensitivity, and the preamplifier noise level can be as low as an equivalent 10^{-4} ms^{-2} for broadband measurements. The maximum level is dependent upon size and construction and can be as high as 10^6 ms^{-2} for small shock accelerometers. Most commercially available accelerometers at least cover the range 10^{-2} ms^{-2} to $5 \times 10^4 \text{ ms}^{-2}$. This range is then extended at one end or the other, depending upon accelerometer type.

The transverse sensitivity of an accelerometer is its maximum sensitivity in a direction at right angles to its main axis. The maximum value is usually quoted on calibration charts and should be less than 5% of the axial sensitivity. Clearly, this can affect acceleration readings significantly if the transverse vibration amplitude at the measurement location is an order of magnitude larger than the axial amplitude. Note that the transverse sensitivity is not the same in all directions; it varies from zero up to the maximum, depending on the direction of interest. Thus, it is possible to virtually eliminate the transverse vibration effect if the transverse vibration only occurs in one known direction.

Accelerometer base strain, due to the structure on which it is mounted undergoing strain variations, will generate vibration signals. These effects are reduced

Figure 2 Beam-type accelerometer using a PVDF film sensing element.

by using a shear-type accelerometer and are virtually negligible for piezoresistive accelerometers.

Magnetic fields generally have a negligible effect on an accelerometer, but large, varying fields may induce a spurious output. The effect of intense electric and magnetic fields can be minimized by using a differential preamplifier with two outputs from the same accelerometer such that voltages common to the two outputs are canceled out. This arrangement is generally necessary when using accelerometers near large generators or alternators.

Accelerometers are generally lightly damped and have a single-degree-of-freedom resonance (characterized by the seismic mass and piezoelectric crystal stiffness) well above the operating frequency range as shown in Fig. 3a. Care should be taken to ensure that high-frequency vibrations do not excite the accelerometer resonance and thus produce preamplifier or amplifier overloading or errors in measurements, especially when no frequency analysis is used. The effect of this resonance can be minimized by inserting a mechanical filter between the accelerometer and its mounting

Figure 3 Typical frequency response of an accelerometer. Solid line is for an accelerometer bolted directly to a solid structure and the dashed line is the result of placing a mechanical filter between the accelerometer and solid structure. (Adapted from Brüel and Kjær.²)

point. This results in loss of accuracy at lower frequencies, effectively shifting the ± 3 -dB error point down in frequency by a factor of 5 (see Fig. 3b). However, the transverse sensitivity at higher frequencies is also much reduced.

The frequency response of an accelerometer is regarded as essentially flat over the frequency range for which its electrical output is proportional to within ± 5 to $\pm 10\%$ of its mechanical input. The lower frequency limit has been discussed previously. The upper frequency limit is generally just less than one third (using the $\pm 10\%$ limit) of the resonance frequency (see Fig. 3a). The resonance frequency is dependent upon accelerometer size and may be as low as 1000 Hz or as high as 180 kHz. In general, accelerometers with higher resonance frequencies are smaller in size and less sensitive.

There are numerous methods of attaching an accelerometer to a vibrating surface. Some are illustrated in ISO 5348³ and Chapter 15 of Hansen and Snyder.⁴ The method used will determine the upper frequency for which measurements will be valid.

Mounting the accelerometer by bolting it to the surface to be measured with a BeCu alloy stud is by far the best method and results in the resonance frequency quoted in the calibration chart. Best results are obtained if a thin layer of silicon grease is used between the accelerometer base and the structure, especially if the mounting surface is a little rough. If electrical isolation is desired, or if drilling holes in the surface is undesirable, a cementing stud may be used with little loss in performance. This stud is fixed to the surface using epoxy or cyanoacrylate adhesive. If electrical isolation is desired, a thin layer of epoxy can be spread on the surface and allowed to dry, and the stud then stuck to the dried layer. Alternatively, the accelerometer could be fixed to the surface directly using adhesive, but this can damage it superficially. An alternative method of electrical isolation if holes are allowed in the test surface is to use an isolated stud with a mica washer.

Beeswax can be used for fixing the accelerometer to the vibrating surface with little loss in performance up to temperatures of 40°C provided only a thin layer is used. Thin double-sided adhesive tape can also be used at the expense of reducing the usable upper frequency limit of the accelerometer by approximately 25%. Thick double-sided tape (0.8 mm) reduces the upper frequency limit by up to 80%. The use of a permanent magnet to mount the accelerometer also affects its performance, reducing its mounted resonance frequency by an amount highly dependent on magnet construction and surface properties. This mounting method is restricted to ferromagnetic materials.

For all accelerometers, the accelerometer cable should be fixed with tape to the vibrating surface to prevent the cable from excessive movement. This will minimize the effect of triboelectric noise, which results from the cable screen being separated from the insulation around the inner core of the cable. This separation creates a varying electric field that results in a minute current flowing into the screen that will be

superimposed on the accelerometer signal as a noise signal. For this reason low noise accelerometer cable should always be used.

Accelerometers generally have a flat zero degree phase between the mechanical input and electrical output signals at frequencies below about one third of the mounted resonance frequency. If accelerometers are heavily damped to minimize the resonance effect, then the phase error between the mechanical input and electrical output will be significant, even at low frequencies. This explains why commercially available accelerometers are usually lightly damped.

Temperatures above 100°C can result in small reversible changes in accelerometer sensitivity of up to 12% at 200°C. If the accelerometer base temperature is kept below 200°C using a heat sink and mica washer with forced air cooling, then it is possible to take measurements on surfaces as hot as 400°C. Without cooling, accelerometers cannot generally be used at temperatures in excess of 260°C. PVDF film accelerometers will not even tolerate this temperature and should not be used above 120°C.

If the test object is connected to ground, the accelerometer must be electrically isolated from it or an earth loop may result, producing a high-level hum in the resulting acceleration signal at the mains power supply frequency (50 or 60 Hz, depending on the country).

Accelerometers should not be dropped on hard surfaces (which can easily produce shocks in excess of 20,000 m/s²) or subjected to temperatures in excess of 260°C. Otherwise permanent damage (such as depolarization, cracking of the brittle piezoelectric element, or melting of the isolation materials), indicated by a significant change in accelerometer sensitivity, will result.

2.2 Velocity Transducers

Velocity transducers are generally one of two types. The least common type is the noncontacting magnetic-type consisting of a cylindrical permanent magnet on which is wound an insulated coil. A voltage is produced by the varying reluctance between the transducer and the vibrating surface. This voltage is proportional to the surface velocity and the mean distance between the transducer and the surface. When nonferrous vibrating surfaces are to be measured, a high permeability disk may be attached to the surface. This type of transducer is generally unsuitable for absolute measurements but is very useful for relative vibration velocity measurements such as needed for vehicle active suspension systems. Another device suitable for vehicle active suspension systems consists of a magnet fixed to the vehicle body and a coil fixed to the suspension. Relative motion between the two produces a coil voltage proportional to the velocity.⁵ This type of device is a subset of the most common general type of velocity transducer consisting of a moving coil surrounding a permanent magnet. Inductive electromotive force (emf), which is proportional to the velocity of the coil with respect to the permanent magnet, is set up in the coil when it is vibrated. In the 10 Hz to 1 kHz frequency

range, for which the transducers are suitable, the permanent magnet remains virtually stationary and the resulting voltage is directly proportional to the velocity of the surface on which it is mounted. Outside of this frequency range, the velocity transducer electrical output is not proportional to its velocity. This type of velocity transducer is designed to have a low natural frequency (below its useful frequency range); thus, it is generally quite heavy and can significantly mass load light structures. Some care is needed in mounting but this is not as critical as for accelerometers, due to the relatively small upper frequency limit characterizing the basic transducer.

The velocity transducers discussed above generally cover the dynamic range of 1 to 100 mm/s. Some allow measurements down to 0.1 mm/s while others extend them to 250 mm/s. Sensitivities are generally of the order of 20 mV/mm s⁻¹. Due to their limited dynamic range they are not as useful as accelerometers. Low impedance, inexpensive voltage amplifiers are suitable for amplifying the signal. Temperatures during operation or storage should not exceed 120°C.

Another type of velocity transducer is the laser Doppler velocimeter, which allows vibration velocity measurement without the need to fix anything to the vibrating surface. Commercially available systems focus a narrow beam of laser light on to a vibrating surface and measure the Doppler shift in the reflected light resulting from motion of the surface. Laser Doppler systems are available that scan surfaces very quickly and then display the entire surface motion on a computer screen. It is even possible to measure vibration along three Cartesian axes simultaneously. Torsional vibration can also be measured using a laser Doppler velocimeter with two laser beams that are directed at a rotating shaft. More details of the principles of operation of laser Doppler velocimeters are available from the manufacturers (e.g., Polytec in Germany). The dynamic range of these instruments has been improving steadily since the first versions became available. Minimum velocity levels that can be measured are approximately 0.01 mm/s and maximum velocities are about 20,000 mm/s peak to peak. Frequency ranges vary with the instrumentation type, but the upper range can be up to 1 MHz with the lower end 0 Hz.

2.3 Displacement Transducers

Although the dynamic range of displacement transducers is typically much smaller than it is for accelerometers, displacement transducers are often more practical at very low frequencies (0 to 10 Hz), where vibration amplitudes are measured in terms of tenths or hundredths of a millimetre, and where corresponding accelerations are small.

The most common type of displacement transducer is the proximity probe. Two types of proximity probes are available, the capacitance probe and the eddy current probe. The capacitance probe relies on the measurement of the change in electrical capacitance between the vibrating machine surface and the stationary probe. The eddy current probe relies on

the generation of a magnetic field at the probe tip by a high-frequency (>500 kHz) voltage applied to a coil of fine wire. This magnetic field induces eddy currents proportional to the size of the gap between the probe tip and machine surface. These currents oppose the high-frequency voltage and reduce its amplitude in proportion to the size of the gap. Typical gap ranges in which the amplitude is a linear function of gap size vary from between 1 and 4 mm for smaller diameter probes to between 2 and 20 mm for larger probes. The carrier amplitude signal is demodulated to give a low-impedance voltage output proportional to gap size over the linear range of the transducer.

Eddy current probes are more common and easier to use than capacitive-type pickups so further discussion will be restricted to the former type. When mounting an eddy current proximity probe to measure the vibration of a rotating shaft, the surface or shaft to be measured must be free of all irregularities such as scratches, corrosion, out-of-roundness, chain marks, and the like. Any irregularity will cause a change in probe gap that is not a shaft position change, resulting in signal errors. This is called mechanical runout.

The shaft material must be of uniform composition all the way round its surface so that the resistivity does not vary as the shaft rotates, resulting in an unwanted electronic noise signal. This is called electrical runout noise. Care should also be taken with the use of plated shafts, as thin plating can allow the eddy currents to penetrate to the main shaft material, resulting in two different material resistivities being detected as well as the rough interface surface between shaft and surface treatment. As probes are generally matched to a particular shaft material, this can lead to calibration problems, as well as electronic noise problems due to the rough interface.

Proximity probes require a power supply and low-impedance voltage amplifier, both of which are generally supplied in the same module. Note that the length of cable between the power supply and probe significantly affects the probe sensitivity.

The dynamic range of an eddy current proximity probe is typically 100:1, although some have a range of 150:1 and others 60:1. The resolution to which the probe can measure varies from 0.02 to 0.4 mm, depending upon the absolute range (2 to 25 mm). The limited dynamic range restricts its practical application to frequencies of less than 200 Hz.

Another commonly used displacement transducer is the linear variable differential transformer (LVDT). This is described in detail Hansen and Snyder.⁴ A typical dynamic range for this type of transducer is about 100:1, with maximum displacements measurable ranging from 1 to 100 mm, depending on the transducer selected.

The frequency range characterizing most commercially available LVDT transducers is dc to 100 Hz. For long stroke (± 15 to ± 100 mm) transducers, the diameter is typically between 12 and 20 mm, with a body length of about three times the maximum stroke (or displacement from center). Short stroke transducers usually have a fixed length not less than 30 to

50 mm. More detail on the principles of operation of these devices are available in publications from commercial suppliers.

A less commonly used displacement transducer is the linear variable inductance transducer (LVIT), which is used for measuring relative displacements, especially in vehicle suspension systems. It is described in detail by Hansen and Snyder⁴ and Moore.⁶

2.4 Strain Sensors

When a structure vibrates either flexurally or longitudinally, its surface is subjected to cyclic strains that can be detected with a strain sensor. Three types of strain sensors will be considered here: conventional resistive strain gauges, PVDF film, and optical fibres.

2.4.1 Resistive Strain Gauges Resistive strain gauges are constructed of a thin, electrical-conducting wire, foil, or semiconductor sandwiched between two plastic sheets, as shown in Fig. 4a. Larger areas at the ends of the grid facilitate connection of cables. The plastic sheets bonded to the active element simplify handling and protect the element from mechanical damage.

Foil strain gauges are produced by photoetching a metallic foil (3 to 5 μm thick). The material used for the metallic element is usually an alloy of nickel and copper (constantan), the exact composition of which is dependent upon the material on which the strain gauge is to be used. Some effort is made to match the temperature coefficient of expansion of the strain gauge with the material on which it is to be used.

Wire strain gauges are produced using metallic wire, 15 to 25 μm in diameter. Foil gauges are easier to make if the gauge length is approximately 6 mm or less, whereas wire gauges are easier for lengths greater than approximately 6 mm. Wire gauges are also more suitable for high-temperature applications, as more suitable materials are available and better mounting techniques can be used.

Semiconductor strain gauges contain a semiconductor element a few hundred micrometres wide and 20 to 30 μm thick, and their operation is based on the piezoresistive effect; that is, mechanical stress applied to a semiconductor will result in a change in resistance as a result of a change in electron mobility. This type of gauge is the most expensive and the least preferred type for most applications, unless a high sensitivity is needed.

The operation of metallic strain gauges is based on the principle that the electrical resistance of a metallic conductor changes if the conductor is subjected to an applied strain. The change in resistance of the strain gauge is partly due to the change in the geometry of the conductor and partly due to the change in the specific conductivity ρ of the conductor material due to changes in the material structure. The change in resistance ΔR of a strain gauge as a fraction of the nominal resistance R_0 for a cylindrical conductor is given by

$$\frac{\Delta R}{R_0} = \varepsilon \left(1 + 2\nu + \frac{1}{\rho} \frac{\partial \rho}{\partial \varepsilon} \right) \quad (1)$$

where ν is Poisson's ratio, ε is the strain imposed on the strain gauge, and the first two terms in parentheses represent the geometrical component. The quantity in parentheses in Eq. (1) is a constant over a wide range of values of ε for materials such as constantan and shapes, which are used in strain gauges. Thus, Eq. (1) can be written as

$$\frac{\Delta R}{R_0} = K \varepsilon \quad (2)$$

where K is the gauge factor (usually in the vicinity of 2).

As the resistance change ΔR is usually a very small value, it cannot be accurately measured directly. The

Figure 4 (a) Strain gauge types and (b) Wheatstone bridge circuit.

most common means of determining ΔR is to insert the strain gauge as one leg in a Wheatstone bridge (see Fig. 4b). The bridge is balanced by varying R_1 to produce zero output, with the vibrating structure at rest. When the structure begins to vibrate, a voltage proportional to the strain (and thus structural vibration bending moment) will appear at the bridge output. Note that the bending moment is the double spatial derivative of the structural displacement.

The bridge output voltage V_0 is related to the change in resistance ΔR of the strain gauge, the bridge dc supply voltage V_s , and the structural strain as

$$\frac{V_0}{V_s} = \frac{\Delta R}{R} = K\varepsilon \quad (3)$$

As V_s is normally about 5 V and K is about 2, the output voltage V_0 is about 10 times the strain level. Thus, 1 μ strain would produce 10 μ V. Clearly, a high-gain, low-noise operational amplifier is needed to amplify the voltage to a usable level if strains as low as a few microstrains are to be measured. Also, the dc power supply to the bridge must be characterized by very low noise levels; often batteries rather than regulated mains power are necessary. The dynamic range of a strain gauge and its associated electrical system is from 2 to 5 μ strain to 10,000 μ strain over a frequency range limited only by the amplifying electronics and the way the gauge is fixed to the structure. The frequency range of general interest is usually limited to dc to 1000 Hz, and this is easily covered with standard circuitry.

In some cases, the sensitivity of the measurement system can be increased by replacing resistances R_3 or R_2 in the Wheatstone bridge with a second strain gauge. If resistance R_2 is replaced with a strain gauge, the two strain gauges in the bridge must be tensioned and compressed out-of-phase with one another for the two effects to add together. This is achieved, for example, by using two strain gauges on opposite sides of a beam to detect flexural vibration. This configuration has the added advantage of minimizing the dc drift in the output signal as a result of temperature changes occurring in the system being measured. If only one strain gauge is used (or if the second one replaces R_3 in the Wheatstone bridge circuit), then a temperature change in the system being measured will cause the structure to expand differently to the strain gauge (as the coefficients of thermal expansion of the test structure and the strain gauge are not exactly matched in practice), thus resulting in a strain gauge output not related to stress in the structure. However, this is rarely a problem when strain gauges are used just to sense vibration, as the frequency of temperature fluctuations is generally well below the frequency range of interest.

When installing strain gauges on a surface for vibration measurement, many factors need to be considered such as adhesive selection, protection of the installed gauge from the environment, and selection of a gauge size appropriate for the task.

Larger gauges average the vibration over a larger surface area and are usually easier to install. Suitable adhesives include cyanoacrylate (superglue) provided the completed installation is covered with a waterproof compound. Other adhesives and protective compounds are available from strain gauge manufacturers.

2.4.2 PVDF Film When bonded to a surface, polyvinylidene difluoride (PVDF) film produces either a charge or a voltage proportional to the strain of the surface. The charge may be amplified by a high-impedance charge amplifier to produce a voltage proportional to the strain. The advantage offered by PVDF film when compared to strain gauges is its ability to act as a distributed sensor and to be shaped so that it senses particular vibration modes, or combinations of modes, if so desired.⁴ For example, if it is desired to control sound radiation, then the sensor could be shaped so that it sensed the surface vibration distribution that contributed most to the sound radiation. When acting as a distributed sensor, PVDF film provides an output charge or voltage proportional to the surface strain integrated over the area covered by the sensor.

The PVDF film is an extremely flexible polymer that can be polarized across its thickness (usually between 9 and 110 μ m) by a strong electric field. It can act either as a sensor or an actuator. Once polarized, PVDF film will provide a charge or voltage when subjected to an applied tensile force or strain. Conversely, it will produce a strain when subjected to an applied voltage, but this must be well below its original polarization voltage. The maximum operating voltage is 30 V/ μ m thickness, and the breakdown voltage at which polarization is lost is 100 V/ μ m thickness. The polarization axis for PVDF film is usually normal to the surface, across the thickness. A detailed analysis of the output of a PVDF sensor as a result of vibration of the surface on which it is mounted is provided in Hansen and Snyder.⁴

Typical thicknesses of PVDF film range from 9 to 110 μ m. However, as shown by the analysis in Chapter 15 of Hansen and Snyder,⁴ it can be seen that if the film is attached to a vibrating surface, the charge produced is independent of the film thickness, and only dependent upon the strain induced by the vibrating surface and the area of film used. On the other hand, the voltage produced is dependent on the thickness but not the area of film.

As a guide to the sensitivity of PVDF film compared to a strain gauge for measuring dynamic strain, a piece 10 mm \times 10 mm will produce a charge of approximately 5.5 pC when subjected to 1 μ strain. A conventional charge amplifier noise floor is approximately 0.003 pC, so the strain detected can be as low as 10^{-9} . This compares very favorably with a strain gauge that is limited to about 10^{-6} . The upper limit of the dynamic strain that can be measured is governed by the tensile and compressive strength and is approximately 0.015, which is similar to a strain gauge.

2.4.3 Optical Fibers The use of optical fibres as strain sensors was first discussed by Butter and

Hocker.⁷ Optical fiber sensing is expensive, requiring a laser and complex signal processing electronics, but for some applications it is the only feasible choice. Such applications include structures subjected to high-level electromagnetic fields, high temperatures and pressures, and/or harsh chemical environments. These sensors are described in detail in Hansen and Snyder.⁴

3 TRANSDUCERS FOR GENERATING VIBRATION

3.1 Hydraulic Actuators

Hydraulic actuators generally consist of a piston in a hydraulic cylinder that has hydraulic fluid openings at each end. Introduction of high-pressure fluid into one end of the cylinder causes the piston to move to the other end, expelling fluid from the opening at that end. Switching the supply of high-pressure fluid to the other end of the cylinder causes the piston to move in the opposite direction.

The most common method to alternate the hydraulic supply from one end of the cylinder to the other is to use a servovalve, which consists of movable spool connected to a solenoid. Applying voltage to the solenoid coil causes the spool to move, which in turn results in the opening and closing of valves responsible for directing hydraulic fluid to either end of the hydraulic cylinder. Note that the servovalve spool is usually maintained in its inactive position with springs at either end. The operation of the servovalve is described in detail in Hansen and Snyder.⁴

One advantage of hydraulic actuators is their large displacement and high force generating capability for a relatively small size. Disadvantages include the need for a hydraulic power supply, which can be inherently noisy, and nonlinearities between the servovalve input voltage and the hydraulic actuator force or displacement output.

3.2 Pneumatic Actuators

Pneumatic actuators are very similar in operation to hydraulic actuators, except that the hydraulic fluid is replaced by air. One advantage of active pneumatic actuators is that they can use the same air supply as passive air springs, which may be mounted in parallel with them. Pneumatic actuators may also be the

preferred option in cases where an existing compressed air supply is available. The major disadvantage of pneumatic actuators is their relatively low bandwidth (less than 10 Hz) due to the compressibility of the air.

3.3 Proof Mass (or Inertial) Actuator

This type of actuator consists of a mass that is free to slide along a track or inside of a coil. The mass is accelerated using an electromagnetic field (see Fig. 5a), so in one sense this type of actuator is similar to an electrodynamic shaker, which will be described in the next section. In this case, the mass is a permanent magnet. The mass can also be accelerated by other means; for example, by connecting it to a ball screw (see Fig. 5b). The proof mass results in a reaction in the ball screw or electromagnetic stator that is attached to the structure to be controlled.

Another type of proof mass actuator is one that imparts moments rather than forces to a structure by control of a rotating mass, which results in reaction moments on the support structure (see Fig. 5c). One problem with linear proof mass actuators is the limited motion of the reaction mass, which becomes more serious when low-frequency vibration modes in a structure are to be controlled.

3.4 Electrodynamic and Electromagnetic Actuators

Electrodynamic actuators or shakers consist of a movable core (or armature) to which is fixed a cylindrical electrical coil. The core and coil move back and forth in a magnetic field that is generated by a permanent magnet (smaller shakers) or by a direct current flowing through a second coil fixed to the stationary portion of the shaker (stator), as shown in Fig. 6a. The movable core is supported on mounts that are very flexible in the axial direction in which it is desired that the core move and rigid in the radial direction to prevent the core contacting the outer armature. To maximize lightness and stiffness, the core is usually constructed of high-strength aluminum alloy and is usually hollow. Mechanical stops are also usually provided to prevent the core from being over driven. In some cases, the driving coil is air cooled.

When a sinusoidal voltage is applied to the drive coil, the polarity and strength of the drive coil magnetic

Figure 5 Proof mass (inertial) actuators: (a) linear, electromagnetic; (b) linear, ball screw; and (c) rotational.

Figure 6 (a) Schematic of an electrodynamic shaker and (b) electromagnetic shaker.

field changes in phase with the applied voltage and so then does the force of attraction between the field coil (or permanent magnets) and the driving coil, resulting in axial movement of the core (or armature).

Electromagnetic actuators are similar in construction to electrodynamic shakers except that the inner core as well as the armature is fixed, (see Fig. 6b). It is constructed by surrounding an electrical coil with a permanent magnet. Supplying a sinusoidal voltage to the coil results in the production of a sinusoidally varying magnetic field that can be used to shake ferromagnetic structures, or structures made from other materials, if a thin piece of shim steel is bonded to them. Clearly, the electromagnetic actuator must be mounted on a rigid fixture, preferably not connected to the structure to be excited.

If the permanent magnet were not used, the attraction force between the coil and the structure being shaken would not vary sinusoidally but would appear like a rectified signal, with most of the excitation energy being at twice the coil driving frequency.

Electromagnetic drivers such as those just described are easily and cheaply constructed by bonding the coil from a loudspeaker driver into the core of the permanent magnet where it is normally located in its at rest condition.

3.5 Magnetostrictive Actuators

The most effective alloy used in these actuators is terfenol-D, with the composition $\text{Tb}_{0.3} \text{Dy}_{0.7} \text{Fe}_{1.93}$. The subscripts refer to the atomic proportions of each element (terbium, dysprosium, and iron). Multiplying these by the atomic weights gives the weight proportions (18, 42, and 40%, respectively). The notable properties of this material are its high strain ability (25 times that of nickel, the only other commonly used magnetostrictive material, and 10 times that of piezoelectric ceramics—see next section) and high-energy densities (100 times that of piezoceramics). Thus, terfenol-D can produce high force levels and high strains relative to other expanding materials. The maximum possible theoretical strain is 2440 μstrain ,

and 1400 μstrain are achievable in practice. The properties of terfenol are discussed in detail in the literature,^{4,8,9} where a complete mathematical analysis is provided.

As an example, for an actuator containing a 50-mm long terfenol rod, the maximum possible displacement will be $50 \times 10^{-3} \times 1400 \times 10^{-6}$ m or 70 μm . In practice, actuators are generally limited to 1000 μstrain (or 50 μm for a 50-mm-long Terfenol rod) to minimize nonlinearity.

As application of a magnetic field of any orientation will cause the terfenol rod to expand, a dc magnetic bias is necessary if the terfenol rod expansion and contraction is to follow an alternating current (ac) input signal into the coil. Thus, a dc magnetic bias supplied either with a dc voltage signal applied to the coil or with a permanent magnet, is required so that the terfenol rod expands and contracts about a mean strain (usually about 500 μstrain). Use of a dc bias current introduces problems associated with drive amplifier design and transducer overheating; thus, it is more common to use a permanent magnet bias.

To optimize performance (maximize the strain ability of the actuator), it is necessary to apply a longitudinal prestress of between 7 and 10 MPa. The prestress ensures that the magnetically biased actuator will contract as much as it expands when a sinusoidal voltage is applied to the drive coil.

Terfenol actuators are usually characterized by a resonance frequency in the few kilohertz range and generally have a reasonably flat frequency response at frequencies below about half the resonance frequency. The actual resonance frequency depends on the mass driven and the stiffness of the terfenol rod. Longer, thinner drives and larger masses result in lower resonance frequencies.

The force output for a clamped actuator may be calculated using $F = EA\Delta L/L$, where E is the elastic modulus (3.5×10^{10} N/m²), A is the cross-sectional area of the terfenol rod (m²), and $\Delta L/L$ is the strain. Thus, a 6-mm-diameter rod operating in a magnetic

Figure 7 Actuator configurations for applying a bending moment to a panel without a reaction mass.

field capable of producing ± 500 μ strain about, the bias value of $+500$ can produce a force of ± 500 N.

Terfenol is very brittle and must be carefully handled. Its tensile strength is low (100 MPa), although its compressive strength is reasonably high (780 MPa). Another important disadvantage is the low displacement capability, which would be a problem in low-frequency vibration control (below 100 Hz). One way around this limitation is to use displacement expansion devices that rely on the lever principle to magnify the displacement at the expense of reduced force output. The main disadvantage associated with magnetostrictive actuators, however, is the hysteresis inherent in terfenol that results in a nonlinear actuation force for a linear voltage input. This results in excitation frequencies being generated that are not related to the voltage input frequencies.

The main advantage of terfenol is its high force capability for a relatively low cost. Electrodynamic shakers capable of the same force capability cost and weigh between 25 and 100 times as much and require a much larger driving amplifier. Thus, another advantage is small size and light weight, which makes the actuator ideal for use in situations where no reaction mass is necessary.

3.6 Shape Memory Alloy Actuators

A shape memory alloy is a material that when plastically deformed in its low-temperature (or martensitic) condition, and the external stresses removed, will regain its original (memory) shape when heated (to about 60°C).¹⁰ The process of regaining the original shape is associated with a phase change of the solid alloy from a martensite to an austenite crystalline structure. Restraining the material from regaining its memory shape can yield stresses of up to 500 MPa (for an 8% plastic strain and a temperature of 180°C).¹¹ Thus if the temperature is cycled, a cyclic force can be generated and used for structural actuation. If the material, nitinol (56% nickel and 44% titanium) is used, it can be heated easily by passing a current through the material and cooled by turning off the current. However, the frequency response is very low; a maximum of 10 Hz can be expected. More details on how to use this material are provided by Hansen and Snyder.⁴

3.7 Piezoelectric Actuators

This type of actuator may be divided into two distinct categories; the thin plate or film type and the stack (shaker) type. The thin type may be further categorized into piezoceramic plates (PZT) or piezoelectric film (PVDF). The thin type is usually bonded to the structure it is to excite and generates excitation by imparting a bending moment to the structure. The thickness ranges from 0.25 to 6 mm. The stack type of actuator consists of many thin layers (about 100, each 0.25 to 1 mm thick) bonded together. It is used in a similar way to an electrodynamic shaker or magnetostrictive actuator, generally applying to the structure a force distributed over a small area.⁴

One problem with piezoelectric actuators (both the thin sheet type and stack type), which is also experienced by magnetostrictive actuators, is their hysteresis property, which means that the expansion as a function of a given applied electric field (or voltage) is dependent upon whether the field level is rising or falling. It is also a nonlinear function of the applied electric field in either direction. This results in nonlinear excitation of a structure attached to one of these actuator types. Thus, if the exciting voltage used to drive the actuator is sinusoidal, the resulting structure motion will contain additional frequencies.

3.8 Electrorheological Fluids

The most common type of electrorheological fluid being investigated commercially is the class of dielectric oils doped with semiconductor particle suspensions. On application of an electric field of sufficient strength, the particles form chains that link across the electrodes, resulting in an apparent change in viscosity (or resistance to flow). Perhaps the most obvious application of these types of fluid in active vibration control is to provide a variable damping force in a semiactive suspension system. Although it is possible to switch the fluids from their inactive to active state in 3 to 5 ms, it takes somewhat longer to reverse the process, thus severely restricting the useful frequency range of active dampers and isolators constructed from these materials. Other problems are associated with the relatively high-voltage requirements (2 to 10 kV) and separation of the fluid to solid particles when the fluid is in its inactive state.

3.9 Magnetorheological Fluids

Magnetorheological fluids (MRFs) are essentially non-colloidal suspensions consisting of a high concentration of magnetically polarizable particles dispersed in a nonmagnetic fluid carrier. The particles are usually iron oxides, and the carrier is usually silicon, oil, or glycerol. When a strong magnetic field is applied, the particles align and result in a large increase in the fluid stiffness. The fluid can respond to magnetic field variations at a rate of up to several hundred hertz, and they can operate in the temperature range of -50 to $+150^{\circ}\text{C}$. These properties make them particularly suitable for use as an active element in vehicle suspension systems. The main disadvantage of these fluids is the settling out of suspension of the magnetic particles when the fluid is in its inactive state for an extended period of time.

4 SMART STRUCTURES

Smart structures contain sensors and/or actuators as an integral part. Passive smart structures contain only sensing elements that allow their state at any particular time to be determined. Such sensors could include piezoelectric film (PVDF) or optical fibers. Active smart structures contain in-built actuators as well as sensors, which enable them to respond automatically to correct some undesirable state detected by the sensors.

Actuators that have been used in laboratory experiments in the past include piezoelectric film or piezoceramic crystal or shape memory alloy. Magnetostrictive terfenol may also be useful for this purpose but is more likely to be bonded to the external surface of structures rather than embedded in them.

Structures that particularly lend themselves to the integration of sensors and actuators are carbon fiber and glass fiber composite structures, which are made by laminating the glass or carbon cloth with a suitable epoxy resin. However, other noncomposite structures can be made into smart structures by bonding actuators and sensors to their surface.

One interesting smart structure is a foam blanket in which small inertial actuators are embedded. The structure has vibration sensors on it that provide a signal to a control system that in turn drives the inertial actuators to minimize the vibration detected by the sensors. The actuators consist of small magnets contained in a plastic tube around which is wound a coil through which the control signal passes.

4.1 Novel Actuator Configurations

One problem with applying piezoceramic stacks, magnetostrictive rods, or hydraulic or electrodynamic actuators to a structure in the traditional way is

the need for a reaction mass and support for the actuator. The need for a reaction mass makes the application of active vibration control using these actuators impractical in many situations. However, the need for this reaction mass can be eliminated by using a more imaginative actuator configuration that applies control bending moments rather than control forces to the structure. For stiffened structures such as aircraft fuselages or submarine hulls, implementation of the actuator configurations is even more convenient.

Two possible actuator configurations that need no reaction mass are illustrated in Figs. 7a and 7b. The first figure illustrates the arrangement where stiffeners already existed on the panel, and the second figure shows an alternative arrangement that might be used if no prior stiffeners existed. The configurations shown for panel vibration control can easily be extended to cylindrical structures such as aircraft fuselages and submarine hulls.

CHAPTER 38

SOUND LEVEL METERS*

George S. K. Wong
Institute for National Measurement Standards
National Research Council Canada
Ottawa, Ontario, Canada

1 INTRODUCTION

Sound level meters are designed to measure sound over a range of frequencies and levels comparable to the range of the human ear. The human ear can sense sound in the frequency range from about 15 to 16,000 Hz and pressure changes in a range with a ratio in excess of 1 to 1×10^7 . Sound level meters measure and display changes in sound pressures in a systematic manner. Sound pressures are compressed logarithmically so that the 1 to 1×10^7 ratio range is expressed as 0 to 140 dB. The display, whether a ballistic meter movement or a digital display that updates only a few times a second, does not show sound pressure changes instantaneously. Instead, it averages the changes in one of several methods to produce a readable number. The two principal methods are exponential averaging and integrating averaging. Optional features that may be included in sound level meters (SLMs) include peak level, peak hold, maximum level, minimum level, noise dose, sound exposure, events, and exceedance levels with statistical distributions and time histories.

*This chapter is based on Chapter 155, Sound Level Meters, by R.W. Krug, in Volume 4, pp. 1845–1854 of *Encyclopedia of Acoustics*, edited by Malcolm J. Crocker, Wiley, New York, 1997.

1.1 Principles of Operation

Exponential-averaging meters (see Fig. 1) measure sound pressure from a microphone. The microphone, amplifier, and weighting circuit limit the frequencies to a prescribed range. The signal is then squared, so positive and negative pressure changes are converted to the square of the input signal.

The time constant is a single-pole low-pass filter with an exponential time constant. The meter may be graduated directly in decibels (uneven scale), which compresses the low end of the scale and expands the high end, or the logarithm of the signal is taken to produce a linear display in decibels.

Integrating-averaging SLMs (see Fig. 2) detect, frequency weight, and square the sound pressure level similar to exponential-averaging SLMs. The squared signal is integrated. The logarithm of the integrated signal has the logarithm of time subtracted from it. Thus, the level is divided by time or averaged over a time period. The level is then displayed on a meter movement or digital display.

Apart from the microphone and amplifier (including preamplifier) shown in Figs. 1 and 2, a computer can emulate nearly all of the succeeding functions with a microprocessor or with a lap-top computer configured as sound pressure level measuring equipment.

Figure 1 Exponential-averaging SLM.

Figure 2 Integrating-averaging SLM.

1.2 National and International Standards

Standard specifications are required to ensure the sound is measured in a systematic and reproducible manner. Any number of frequency weightings, time constants, and integration methods could be used. Standards prescribe specific methods of measuring sound, and each generation of standards that have different tolerance limits for measurements, such as A-weighted levels, will make it difficult to correlate data on hearing conservation collected with older SLMs that satisfied the standards of the day. In view of the existence of a large number of older SLMs that are still operational and may be in use, it may be worthwhile to discuss briefly the requirements of some older standards. Some of the older and more recent SLM standards are listed below:

- ANSI S1.4-1983¹ and ANSI S1.4A-1985 Amendment to S1.4: Specification for sound level meters
- ANSI S1.25-1978, 1991²: Specification for personal noise dosimeters
- IEC 60651-1979³: Sound level meters
- IEC 60804-1984⁴: Integrating-averaging sound level meters
- IEC 61252-2002⁵: Specifications for personal sound exposure meters
- IEC 61672-1, 2002⁶: Sound level meters—Part 1: Specifications
- IEC 61672-2, 2003⁷: Sound level meters—Part 2: Pattern evaluation tests
- IEC 61672-3, 200X (under development): Sound level meters—Part 2: Periodic verification

The above International Electrotechnical Commission (IEC) 61672 series have superseded some of the older SLM standards, and the American National Standards Institute (ANSI) S1.4 is currently under revision. Terminology used in this chapter has been defined in the above standards.

The ANSI S1.4-1978 and the IEC 60651-1979 both specify exponential-averaging SLMs. They are similar except for the directional specifications of the microphone (see Section 2.2). Both specify three accuracy types of meters: type 0, type 1, and type 2. Type 0 instruments are the most accurate and are intended as laboratory standards. Type 1 instruments are intended for laboratory or field use where the acoustical environment can be closely specified and/or controlled. Type 2 SLMs are suitable for general field applications. Type 3 SLMs are specified in IEC 60651-1979. They are of low accuracy and are intended for sound surveys and with little capability to measure impulsive sounds.

The IEC 60804-1984 specifies type 0, type 1, type 2, and type 3 integrating-averaging SLMs. The ANSI S1.25-1991 personal noise dosimeter and the personal sound exposure meter specify instruments intended to be worn on a person to measure noise exposure. They specify only limited-range, single-frequency-weighting, type 2 instruments.

The IEC 61672-1, 2002, specifies class 1 and class 2 instruments. This relatively new standard eliminated

type 0 and type 3 instruments. Although the design goal of the A-weighting requirements are unchanged but the tolerance limits for class 1 SLMs has been changed to minus infinity at high frequency above 16 kHz (see Section 3.2). This reduces the capability to capture higher harmonics during measuring impulsive sounds.

2 MICROPHONES

Microphones are transducers that convert changes in sound pressure to an electrical signal. As is typical of many transducers, the microphone is likely to be the most critical, fragile, and expensive part of the instrument. Its response is likely to change with frequency, direction, temperature, absolute pressure, time, and several other factors. As such, it is important to appreciate the limitations and work with them to achieve accurate and reliable response. The selection of microphones⁸ is very important for acoustical measurement. For critical applications it is important to understand that the sensitivity of condenser microphones varies with barometric pressure, and this variation that changes with frequency can be corrected.^{9,10}

2.1 Types

Sound level meters use several different microphone types. Three types are most commonly used: piezoelectric (ceramic) and two types of air condensers (polarized and electret). In view of the importance of potential hearing loss due to high-frequency sounds¹¹ the MEM (microelectromechanical) microphone may be used in future high-frequency SLMs that are under development in Germany.

Ceramic Ceramic microphones operate on the principle that piezoelectric materials will generate a voltage when subject to force changes. Ceramics are relatively low cost, have relatively low internal electrical noise, and, compared to other microphones, are quite rugged. They are quite sensitive to vibrations if not mounted properly. The frequency response of ceramic microphones is not as flat as other types, and, as a result, they are often only used with type 2 SLMs.

Condenser The capacitance will change if the separation between two plates is changed. Condenser or capacitor microphones are constructed with one plate of the capacitor made with a very light material that can move when subjected to changes in air pressure. A high voltage is connected via a high impedance to the other plate of the capacitor. Since charge on a capacitor is equal to the capacitance times the voltage, if the capacitance changes and the charge remains constant, the voltage also will change. Condenser microphones tend to be accurate and stable and have a wide, well-defined frequency bandwidth. They are relatively fragile and must be protected from hostile environments and high humidity.

Polarized air condenser microphones require an external voltage often in the range of 200 V. Sensitivity is a function of this voltage that must be well regulated.

Figure 3 Examples of (a) free-field and (b) random-incidence half-inch microphones at 0° and 90° used in type 2 SLMs.

Permanent charged or electret microphones have permanent charge built into a plastic membrane. Response is similar to the polarized microphones.

MEM These microelectromechanical systems (MEMS) microphones have not been used in SLMs as such, but with their fast progress in development it is worth mentioning here to anticipate future possible application in miniaturization and special high-frequency sound level meters. MEMS are tiny microphones (as small as $1.6 \times 2.8 \times 6$ mm) with their diaphragm edged from a single piece of silicon. With sophisticated chemical edging techniques, microphone backplate and possibly other electronics can be incorporated in a very small package and mass produced at a very low cost. There are many problems to be solved such as internal noise, frequency response, sensitivity stability, and dynamic range. Nonetheless, the development of a SLM the size of a matchbox may be closer than we anticipated.

2.2 Microphone Response

Microphone response changes with frequency. Microphones roll off below a couple of hertz to zero sensitivity at 0 Hz. At high frequencies the diameter of the microphone diaphragm is an appreciable part of a wavelength. As a result, the microphone rolls off at high frequencies and changes with the direction in which the microphone is pointed relative to the sound source. In general, microphones with smaller dimensions have better high-frequency response but also less sensitivity.

Free Field Free-field microphones are intended to measure sound in an open space free from reflections. The microphone should be pointed directly at the noise source at a 0° incidence. At 0° incidence the frequency

response is close to flat over the widest frequency range. High-frequency sound arriving from other angles may be somewhat attenuated (see Fig. 3). The IEC^{3,4,6,7} specifies SLMs with free-field microphones.

Random Incidence Random-incidence microphones are intended to measure sound in a diffuse field where the sound is arriving from all directions such as inside a noisy plant or in an area with many reflections. Random-incidence microphones have the flattest response if pointed at about a 70° angle to the noise source. High-frequency noise arriving at angles less than 70° will cause the SLM to read somewhat higher, while angles greater than 70° will generally read somewhat lower (see Fig. 3). The ANSI specifies that SLMs shall use random-incidence microphones. (For more information on free-field and random-incidence measurement, see Chapters 6 and 17 in Ref. 8.)

Pressure Pressure microphones are intended to measure sound in a closed cavity. Its response is often similar to the response of a random-incidence microphone. SLMs are sometimes designed with special circuitry to correct a free-field microphone for random-incidence application.

3 FREQUENCY WEIGHTING

3.1 Standard Weightings

Frequency weightings have been standardized.¹² SLM standards IEC 60651-1979 and ANSI S1.4-1983 specify standard frequency-weighting networks such as A-, B-, and C-weighting (see Fig. 4).

A-weighting is intended to simulate the response of a nominal human ear at 40 phons. It is also considered by many regulations in many countries to be the best weighting for predicting hearing loss due to noise exposure. The SLMs, personal sound exposure meters,

Figure 4 Frequency weighting curves.

and noise dosimeters use A-weighting to determine the effects of noise on humans. See Eq. (2).

B-weighting is intended to simulate the response of a nominal human ear at 70 phons. It is not widely used and has been omitted in the new standards.

C-weighting is intended to simulate the response of a nominal human ear at 100 phons. It is flat over most of the audible frequencies and is down 3 dB at 31.6

and 8000 Hz. Since it is flat over the audible range, it is often used to measure acoustical emission of machinery. It is also used to specify hearing protectors and to measure peak sound pressure level. See Eq. (1).

D-weighting was developed to measure noise from jet aircraft that have a perceived noise level that is higher than the level measured with A-weighting. It is not widely used and it has been dropped from current standards.

Flat or linear response is sometimes included in SLMs. Its frequency response is normally flat between two frequencies. The frequency response is very similar to C-weighting, with the response rolling off at the low end at a couple of hertz and at the high end at several tens of kilohertz. It has been replaced by the Z-weighting in current standards.

In IEC 61672, the A- and the C-weightings are specified, and the **Z-weighting** (or flat) defines a flat response with cutoff frequencies selected by the manufacturer of the SLM.

3.2 A-Weighting Tolerance Limits

In A-weighted level measurements it is important to understand the tolerance limits of an SLM. These tolerance limits play an important role in the indicated sound pressure level that may be quite different from the actual sound pressure level being measured. The class 2 tolerance limits (IEC 61672 and ANSI S1.4) are shown in Fig. 5. The design goal of the A-weighting

Figure 5 Class 2 (type 2) A-weighting tolerance limits.

is shown by the full line of the graph to 100 kHz. However, after 8 kHz the tolerance limit is at minus infinity. The sound energy above 8 kHz may be lost depending on the capability of the microphone and the electronic circuit. Since class 2 instruments are the workhorse of noise measurement related to hearing conservation and noise control program, one can imagine the result obtain with a class 2 instrument during the survey of factories and mines that usually have sounds of impulsive nature with harmonics that well exceed 8 kHz. The level measured by a class 2 instrument in an impulsive environment will be much lower. The A-weighting tolerance limits for class 1 instruments are shown in Fig. 6. For IEC 61672, after 16 kHz the tolerance limit is at minus infinity, which is an improvement from class 2 instruments. However, there is evidence¹¹ pointing to hearing loss due to high-frequency sounds. Removing the harmonics after 16 kHz is not helping hearing conservation programs that rely on SLMs to provide the correct sound pressure levels. It is important to point out that for ANSI S1.4A the A-weighted tolerance limits are much tighter, and it is capable of capturing sound energy beyond 20 kHz. See Fig. 6.

3.3 Weighting Equations

The equations for frequency responses for A- and C-weighting are

$$W_C(f) = 20 \log \left[\frac{f_4^2 f^2}{(f^2 + f_1^2)(f^2 + f_4^2)} \right] - W_{C1000} \quad (1)$$

$$W_A(f) = 20 \log \left[\frac{f_4^2 f^4}{(f^2 + f_1^2)(f^2 + f_2^2)^{1/2} \times (f^2 + f_3^2)^{1/2}(f^2 + f_4^2)} \right] - W_{A1000} \quad (2)$$

where W_{C1000} and W_{A1000} the normalization constants, rounded to the nearest 0.001 dB, are -0.062 and -2.000 dB, respectively, representing the attenuation necessary to provide frequency weighting of zero decibels at 1000 Hz for the C- and the A-weightings, respectively, and $f_1 = 20.60$ Hz, $f_2 = 107.7$ Hz, $f_3 = 737.9$ Hz, and $f_4 = 12194$ Hz.

4 SQUARING AND AVERAGING

The instantaneous level at the input of the squaring circuit is converted to a level proportional to the square of the level. It is interesting to note that if the input

Figure 6 Class 1 (type 1) A-weighting tolerance limits.

pressure varies over 60 dB or 1000:1, the output must vary over a range of 1: 1×10^6 .

The parameter p_a at the output of the squaring circuit can be found as

$$L_{\text{inst}} = 10 \log(p_a^2/p_o^2) \quad (3)$$

where L_{inst} is the instantaneous level in decibels and (p_a^2/p_o^2) is the ratio of the squared instantaneous A-weighted sound pressure to the squared reference sound pressure at 20 μPa .

4.1 Exponential Averaging

A low-pass filter is placed after the squaring circuit to smooth out the instantaneous fluctuation and make it possible to read the level on a meter or digital display. Fast and slow responses are specified by several SLM standards and impulse response I , which is no longer specified in IEC 61672-1, but imbedded in many existing SLMs, can be found in IEC 60651-1979.

Time Constants *Slow (or S)* is specified as a 1-s time constant. Slow is used for measuring sound where an estimate of the average sound level is needed and the fluctuations are too fast to follow with a fast time constant. Slow is specified by the Occupational Safety and Health Administration (OSHA) and the Department of Defense (DOD) in the United States for measuring noise dose.

Fast (or F) is specified as a 0.125-s time constant. Fast follows fluctuations in sound levels better than slow but may fluctuate too much to be read. Fast is often used to measure transient noise such as vehicle passby noise.

Impulse (or I) is specified in IEC 60651-1979 as a 0.035-s time constant followed by a peak detector with a 1.5-s decay time such that the indicator will rise very rapidly to increasing levels but decay slowly when the level decreases. It is used primarily in Germany and a few other countries to measure highly impulsive noise.

4.2 Peak, Maximum, or Minimum Hold

Sound level meters often include additional functions to measure the highest instantaneous level as well as the highest and lowest level after the time constant circuit. These functions can normally be reset to allow detection of the next level.

Peak is the highest instantaneous level. Peak is detected before the time constant circuit. It may have a different frequency weighting than the weighting used to calculate sound pressure level and other levels. Peak signals respond to pulses as short as 50 μs . For a sine wave, the peak level is 3 dB higher than the root-mean-square (rms) level. The tone burst shown in Fig. 7 would have a peak reading of 103 dB.

Maximum and minimum levels are the highest and lowest levels detected after the time constant circuit. The tone burst shown in Fig. 7 has, after a few cycles, a fast maximum of 100 dB and a slow maximum of 96.6 dB. The minimum level for fast is 65.3 dB and for slow is 90.1 dB.

Response to Tone Burst On a logarithmic scale, the time constant will cause the display to change faster for an increase in level than for a decrease in level [see Eqs. (4) and (5)]. The maximum rates of decay for a big decrease in level are 4.34 dB/s for slow, 34.74 dB/s for fast, and 2.90 dB/s for impulse. The maximum response to a single tone burst relative to

Figure 7 Slow, fast, SEL, and L_{eq} responses to tone burst.

the continuous level of the same tone is

$$L_{\text{on}} = L_{\text{tb}} - 10 \log(1 - e^{-T_1/\tau}) \quad (4)$$

The response when a tone is turned off is

$$L_{\text{off}} = L_{\text{on}} - 10 \log(1 - e^{-T_2/\tau})$$

$$L_{\text{off}} = L_{\text{on}} - 4.3429448 \frac{T_2}{\tau} \quad (5)$$

The integrated sound level of an integral number of tone bursts is

$$L_{\text{eq}} = L_{\text{tb}} - 10 \log\left(\frac{T_1}{T}\right) \quad (6)$$

where L_{tb} is the level of tone burst, T_1 the duration of tone burst, T_2 the time from the end of a continuous tone, T the time from the start of one tone burst to the start of the next tone burst ($= 1$ per repetition frequency), and τ an exponential time constant.

4.3 Integrating Averaging

Equivalent Sound Pressure Level Integrating SLMs, combine all the sound pressures between the start and end of an integration period. [See Eq. (7).] The equivalent sound pressure level (L_{eq}) is the logarithmic average of the squared instantaneous pressures. While the exponential-averaging SLM display depends on what the sound level was immediately preceding the time it was read, integrating-averaging SLMs weigh equally all the sound from the start to the end of the integration time. As can be seen in Fig. 7, exponential-averaged SLMs keep changing when measuring discontinuous sound. Equivalent sound pressure level meters quickly settle to an average level. As a rule of thumb, the L_{eq} level should be within 0.1 dB of the final value after as many minutes as the time between impulses in seconds.

In theory, integrating do SLMs not have a time constant. In practice, some do exponentially average the squared pressure before doing the integration. If the integration time period is long compared to the time constant, the exponential circuit makes little difference. If a loud noise occurred shortly before the start time or shortly before the end time, part of that noise may be included or excluded:

$$L_{\text{eq}} = L_{\text{Aeq},T} = 10 \log \frac{1}{T} \int_{T_1}^{T_2} \frac{p_a^2(t)}{p_o^2} dt \quad (7)$$

$$\text{SEL} = L_{\text{EA},T} = 10 \log \int_{T_1}^{T_2} \frac{p_a^2(t)}{p_o^2} dt \quad (8)$$

where p_a is the instantaneous A-weighted sound pressure (for weighting other than A-weighting the subscript is changed) and T is the time between the

start and end times T_1 and T_2 (for the sound exposure level (SEL) the time is always in seconds).

Sound Exposure Level The SEL is similar to L_{eq} in that pressure is integrated over the measurement period [See Eq. (8).] The SEL measures the total energy and normalizes it to 1 s. The SEL is equal to L_{eq} after 1 s. If the L_{eq} is steady with time, the SEL will be 3 dB greater than L_{eq} after 2 s and 6 dB greater after 4 s, and increase by 3 dB whenever time doubles. The SEL is used to measure the total energy in an event independent of the time duration of the event.

Short Equivalent Sound Pressure Level Short L_{eq} is an L_{eq} value computed at very short intervals, perhaps every $\frac{1}{8}$ or $\frac{1}{16}$ s, and stored in memory for later analysis. Data in memory can then be used to calculate a number of sound descriptors such as L_{eq} , SEL, exposure, exceedance levels, sound pressure level, and maximum and minimum levels.

Equivalent Sound Pressure Level per Day and Time-Weighted Average

The term $L_{\text{ep},D}$ is the equivalent sound level per day, and TWA is the time-weighted average. Both $L_{\text{ep},D}$ and TWA are similar to SEL except the integration is averaged over 8 h instead of 1 s. The level will be less than the L_{eq} level for time periods less than 8 h and greater than the L_{eq} level after 8 h. The $L_{\text{ep},D}$ and TWA are used to measure worker noise exposure during a work day. It is assumed that workers who work less than 8 h can be exposed to higher noise levels during the time they are working without increasing their risk of noise-induced hearing loss. The parameter $L_{\text{ep},D}$ is used in the European community while TWA is used in the United States. If the level is constant, $L_{\text{ep},D}$ will increase by 3 dB if the time is doubled. Also, $L_{\text{ep},D}$ is 44.59 dB less than SEL. The TWA may use different doubling or exchange rates. For OSHA compliance, it will increase by 5 dB if the time is doubled.

5 OPERATING RANGE

Ideally, an SLM should accurately measure all sounds from the noise floor to overload regardless of the temporal nature of the sound. While SLMs are available that accurately measure all sounds over a wide range, many SLMs that meet the older standards have very limited range, particularly when measuring transients.

In IEC 60651-1979 and ANSI S1.4-1983, the requirements for steady and transient response are very limited. Accurate steady-level response is only required over a 10-dB range, and transient response is only required for one tone burst. As many instruments made since these standards were issued barely meet the minimum requirements of the standards, much of the data taken with these instruments may be of little value.

The standards IEC 60651-1979 and ANSI S 1.4-1983 state that the accuracy of instruments shall be within ± 0.4 , ± 0.7 , and ± 1.0 dB for types 0, 1, and 2 instruments, respectively. This accuracy is

required only for steady-tone sounds arriving from the reference direction under reference conditions of pressure, temperature, and humidity. Also, it is required only on one primary indicator range over a 10-dB span.

The SLM standards requirements for tone burst require only that type 1 and type 2 instruments be within tolerance at one point. On fast response only 0.2-s tone bursts and on slow response only 0.5-s tone bursts are required to be accurately measured. Unfortunately, there are many instruments on the market that only meet the standard for this one tone burst. If a noise burst is shorter than specified by the standard, the instruments read low or ignore the burst completely.

The standard IEC 60804-1984 expands the linearity range to 70, 60, and 50 dB for type 0, 1, and 2 instruments, respectively. It also requires tone bursts, as short as 0.001 s to be measured within ± 0.5 , ± 0.5 , and ± 1.0 dB for type 0, 1, and 2 instruments, respectively. The standards for personal sound exposure meters and noise dosimeters follow the IEC 60804-1984 type 2 specifications. While this range may not be accurate for very short duration sound burst or for wide level changes, it is sufficient for most noise measurements.

The new IEC 61672-1 specifies only class 1 and class 2 instruments. The tolerance limits for performance include allowances for the expanded uncertainties of measurement that was tabulated for each requirement discussed in the standard. For example, at 250 Hz, the tolerance limits specified for weighted measurements for class 1 instruments is ± 1.4 dB. The corresponding expanded uncertainty allowed is 0.4 dB. (The corresponding tolerance limits specified in IEC 60651 is ± 1.0 dB without allowance for uncertainty of measurement). At 1 kHz (the reference frequency), the design goal for all frequency weightings is 0 dB with corresponding tolerance limits (with expanded uncertainties of measurements included) of ± 1.1 dB for class 1 and ± 1.4 dB for class 2 instruments.

5.1 Linearity Operating Range

The linearity range is specified for continuous sound pressure levels. Ideally the instrument should meet the linearity requirements on all ranges, although additional tolerance is allowed on ranges other than the primary indicator range. With IEC 60651, instruments are required to be linear over a range of frequencies from 31.5 Hz to 8 kHz.

In IEC 61672, level linearity applies over the total range for any frequency within the frequency of the sound level meter and for any frequency weighting or frequency response provided. At 1 kHz, on the reference level range the linear operating range shall be at least 60 dB, and the adjacent ranges shall overlap by at least 30 dB for SLMs that measure time-weighted sound levels, and at least 40 dB for SLMs that measure time-average sound levels or sound exposure levels. These new level linearity requirements have eliminated the discussion on dynamic range.

5.2 Dynamic Range

With previous standards such as IEC 60651 and IEC 60804, dynamic range, often called pulse range, determines the meter's performance when the sound level is not continuous. Ideally, it should be the same as the linearity range. Integrating SLMs are required to have 70, 60, or 50 dB pulse range for types 0, 1, and 2 meters, respectively. Exponential-averaging meters may be very limited in dynamic range capabilities.

5.3 Overload Indicators

Integrating-averaging SLMs and exponential-averaging SLMs are required to have overload detectors to indicate when an overload has occurred. The overload can occur at several places in the meter, and the overload detector may be required to measure several points. Different SLMs have their own implementation for overload indicators. It is best to consult the operating manual to obtain more details on their operation.

5.4 Noise Floor

The lowest level an instrument can read is determined by the noise floor. Noise may be generated in the microphone, its preamplifier, or the electronics of the meter. As a general rule, the lowest level an SLM can measure with 1-dB accuracy is 6 dB above the noise floor. For 0.1-dB accuracy the level must be 16 dB above the noise floor. If the noise floor is well behaved, it is possible to measure lower levels and calculate the actual noise level by logarithmically subtracting the noise from the signal on a mean-square basis. This technique is most useful when measuring sound that can be turned on and off, such as calibrating pure-tone audiometers [see Eq. (9)]:

$$L = 10 \log(10^{(L+N)/10} - 10^{N/10}) \quad (9)$$

where N is the noise floor, $L + N$ the measured level including the noise, and L the level without the noise.

5.5 Threshold Circuits

It is sometimes desirable not to include sounds below a threshold level in the noise calculations. An example is excluding background noise when measuring the noise of an aircraft flyover. The OSHA regulations allow exclusion of noise below certain threshold levels.

Thresholds of noise dosimeters are placed after the time constant circuit and are well defined. Other threshold levels are not well defined, and the user must consult the meter-operating manual to determine exactly how the threshold works.

5.6 Reference Environmental Conditions

IEC 61672-1 specifies reference conditions for specifying of SLMs performance as:

Air temperature: 23°C,
Static pressure: 101.325 kPa
Relative humidity: 50%

6 DISPLAYS AND OUTPUTS

6.1 Analog and Digital

Conventional SLMs use an analog ballistic meter movement to display the sound level. Historically, the conversion to decibels was accomplished by scale graduations. This resulted in a scale with the numbers very close together on the left or lower end and separated on the high or upper end. Such scales were only useful over about a 20-dB range. When meter manufacturers included the logarithmic conversion in the meter electronics, analog meter scales of 30 or more decibels are possible with equal space per decibel. Although digital displays are now widespread, many users still prefer the analog display for ease of reading and detecting changes.

Digital displays offer wide range, and the numbers are easy to read down to a fraction of a decibel. These displays are difficult to read and interpret when used with exponential-averaging meters. If the sound level is not constant, the display will be different each time it updates. It is also necessary to consult the owner's manual to determine if the displayed number is the maximum level, the average level, or the level at the end of the update. Since a display that updates once a second can change 30 or more decibels during that second, it is important to know what is displayed.

6.2 Auxiliary Equipment

Auxiliary outputs are sometimes provided to connect the SLM to other equipment. Consult the operating manual before connecting to make sure the two pieces of equipment are compatible. In general, if a class 2 device such as a filter is connected to a class 1 SLM, the combination is considered as class 2.

7 CALIBRATION

It is recommended that SLMs be checked before and after every use with an acoustical calibrator. Manufacturers' recommendations should be followed. Normally, checking consists of removing the windscreen if any, carefully sliding the calibrator over the microphone, and reading the level. Care must be taken to ensure there is a good seal between the microphone and the calibrator or errors will result. If a calibration has changed by a few tenths of a decibel, it can normally be adjusted to the correct level.

Acoustical calibrators check only the reading at one or at a few frequencies and levels. It is possible for

a check to detect no change at one frequency and the SLM can be out of tolerance at another. If a microphone develops a pin hole air leak, the level may not change dramatically at 1000 Hz but may change considerably at other frequencies. Therefore, if daily checks require more than a few tenths of a decibel of corrections, it may be a sign of a much larger deviation at other frequencies. Good procedure recommends SLMs be calibrated at regular time intervals, such as yearly depending on the usage, by an accredited laboratory to ensure the instrument remains within the tolerance required by standards.

8 OTHER TYPES OF SOUND LEVEL METERS

8.1 Dosimeters and Personal Sound Exposure Meters

A special type of meter for measuring noise is the dosimeter or personal sound exposure meter. A block diagram of a noise dosimeter is shown in Fig. 8. An exposure meter would have a similar block diagram except the time constant, threshold, and exponent circuits would be omitted.

The instruments measure noise according to

$$E = \int_0^T p_a^2 dt \quad (10)$$

$$\text{DOSE} = \frac{100}{T_c} \int_0^T 2^{(L-L_c)/ER} dt \quad (11)$$

where E is exposure, p_a the A-weighted sound pressure, T_c the criterion time (normally 8 h), L_c the criterion level, and ER the exchange rate or doubling. In SI (International System units, exposure is measured in pascal-squared seconds ($\text{Pa}^2 \cdot \text{s}$). For convenience, exposure in personal sound exposure meters is expressed in pascal-squared hours. Exposure to 85 dB for 8 h is approximately equal to one pascal-squared hour ($\text{Pa}^2 \cdot \text{h}$).

Dose is another method of measuring noise exposure, with the results expressed as a percentage of a criterion exposure. In the United States, OSHA, defines 100% dose as the equivalent of a level of 90 dB for 8 h with a 5-dB exchange rate after the time constant. Other regulations may use different criterion levels and

Figure 8 Noise dosimeter.

exchange rates. Since dose combines different levels with 5-dB (OSHA) or 4-dB (DOD) exchange rates, after the time constant circuit, the time constant will change the calculated dose. A slow time constant will produce a higher dose than a fast or no time constant if the sound level is not constant. While Eqs. (10) and (11) appear quite different, they are similar. If the exchange rate is 3 dB, the criterion level is 90 dB, and criterion time is 8 h, then $100\% \text{ dose} = 3.2 \text{ Pa}^2 \cdot \text{h}$.

9 OPTIONS

A number of additional devices may be built-in or connected to SLMs to expand their performance. Some of the measurements and options include acceleration, velocity, displacement, reverberation, signal analysis such as fast Fourier transform (FFT) and narrow band analysis, structural analysis, data acquisition, time capture, tracking filters, sound intensity, and sound power.

CHAPTER 39

NOISE DOSIMETERS

Chucri A. Kardous
Hearing Loss Prevention Section
National Institute for Occupational Safety and Health
Cincinnati, Ohio

1 INTRODUCTION

Noise-induced hearing loss is one of the most prevalent occupational illnesses in the world, but it is also the most preventable. Noise dosimeters have been used extensively over the past two decades to document noise exposures and ensure compliance with rules and regulations developed by various international organizations and regulatory agencies. In the United States, such dosimeters are required to comply with the American National Standards Institute (ANSI) Specification for Personal Noise Dosimeters S1.25–1991 (R1997), which states that dosimeters should be suitable for measurement of impulsive, intermittent, and continuous noise. Noise dosimeters measure and store sound pressure levels and, by integrating these measurements over time, provide a cumulative noise exposure reading for a given period. Dosimeters can function as personal or area noise monitors. In occupational settings, personal noise dosimeters are often worn on the body of a worker with the microphone mounted on the middle-top of the person's most exposed shoulder.

2 PRINCIPLE OF OPERATION

A dosimeter is a battery-powered, portable instrument, derived directly from sound level meters (SLM) to

automate the measurement and calculation of the percentage of the maximum permissible daily noise dose. It consists of a microphone that senses the sound pressure and produces an electrical signal. The output signal is amplified and fed into a frequency-weighting network (most typically, A-frequency weighting). The signal is then squared (sound pressure level is a function of pressure squared) and exponentially averaged with a specified time constant to establish a moving average window in time. The output sound level signal is fed into an integration section (an exponent circuit, threshold circuit, and integrator) that performs the algorithm necessary to compute the percentage criterion exposure (noise dose) according to a particular exchange rate, threshold level, and criterion sound level. The output is indicated as a percentage criterion exposure corresponding to the accumulated data at the completion of the measurement by the indicator circuit. The block diagram for the functional elements of the dosimeter is shown in Fig. 1.

2.1 Noise Dose

Noise dosimeters compute a percentage criterion exposure or noise dose. Noise dose is the quantity that is expressed as a percentage of the maximum permissible daily exposure to noise. Noise dose is

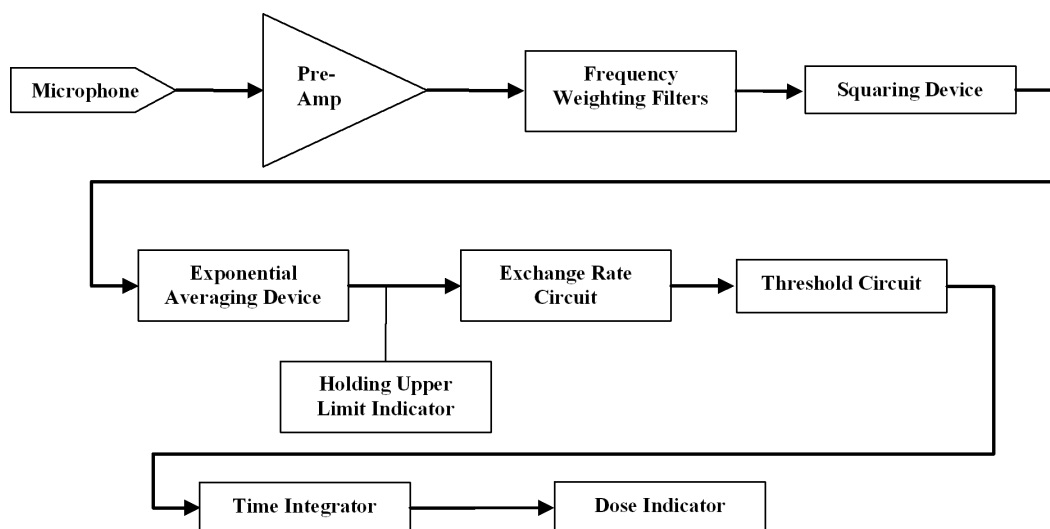

Figure 1 Block diagram of the essential elements of a noise dosimeter.

used in regulations to quantify exposure to noise in the workplace to protect against noise-induced hearing loss. ANSI S1.25 standard defines noise dose by the following mathematical equation:

$$D(Q) = \frac{100}{T_c} \int_0^T 10^{[(L_A(t) - L_c)/q]} dt \quad (1)$$

where $D(Q)$ = noise dose for exchange rate Q

T_c = criterion sound duration = 8 h

T = measurement duration in hours

t = running time in hours

$L_A(t)$ = slow (or fast) A-weighted sound level in decibels (dB) when the sound level is greater than or equal to a user-selectable threshold sound level, or equals $-\infty$ when the A-weighted sound level is less than the threshold level

L_c = criterion sound level (in dB) specified by the manufacturer

Q = exchange rate (in dB) (can be 3, 4, or 5 dB); and $q = Q/\log(2)$ is parameter that determines the exchange rate

Exposure to a sound level that is equal to the criterion level L_c for a measurement time period equal to the criterion duration T_c yields a noise dose of 100%.

The Occupational Safety and Health Administration (OSHA) guidelines provide an alternate method for computing dose when the work shift noise exposure is composed of two or more discrete time periods of noise at varying levels. The total noise dose in percent is then defined by

$$D = 100 \left[\frac{C_1}{T_1} + \frac{C_2}{T_2} + \cdots + \frac{C_i}{T_i} + \cdots + \frac{C_N}{T_N} \right] \quad (2)$$

where C_i is the total time of exposure at a specified A-weighted sound level, and T_i is the reference duration of noise exposure at that sound level that produces a dose of 100%.

The values for T_i are given in Table G-16a in Appendix A of the OSHA 29CFR 1910.95 regulations. A portion of Table G-16a is shown in Table 1. Table G-16a is derived from the following expression:

$$T_N = \frac{T_c}{2^{(L-L_c)/ER}}$$

or, for OSHA regulations

$$T_N = \frac{8}{2^{(L-90)/5}} \quad (3)$$

where L is the *slow* A-weighted sound level. L_c is the criterion or threshold level (90 dB), and ER is the exchange rate (5 dB).

Table 1 Permissible A-weighted Noise Level Exposures

Exposure Level, Slow (dB)	Duration per Day (h)
90	8
92	6
95	4
97	3
100	2
102	1.5
105	1
110	1.5
115	0.25 or less

From OSHA Table G-16, 29CFR 1910.95 (A).

2.2 Exchange Rate

Exchange rate is defined in ANSI S1.25 as “the change in sound level corresponding to a doubling or halving of the duration of sound level while a constant percentage of criterion exposure is maintained.” Dosimeters may be programmed to accept different exchange rates when performing their computations. OSHA requires the 5-dB exchange rate in its guidelines, while the National Institute for Occupational Safety and Health (NIOSH), the American Conference of Governmental Industrial Hygienists (ACGIH), and most international standards recommend the use of the 3-dB (equal-energy rule) exchange rate.^{1,2}

2.3 Criterion Sound Pressure Level

Criterion sound level is the A-weighted sound level that corresponds to the maximum permitted daily exposure (dose of 100%) to noise if continually applied for the criterion time (typically 8 h). Criterion sound level also refers to occupational exposure limits specified by standards and regulations. The current OSHA permissible exposure limit (PEL) or criterion level is an A-weighted sound pressure level 90 dB. ACGIH and most international standards use the 85-dB criterion level, which is also the NIOSH recommended exposure limit (REL).

2.4 Threshold Sound Level

Threshold sound level, in decibels, is the sound level specified by the manufacturer of a noise dosimeter below which the instrument produces no dose accumulation. The current OSHA threshold level is set at 80 dB. The International Electrotechnical Commission (IEC) recommends a 40-dB threshold level.³

3 SOUND EXPOSURE MEASUREMENTS

Noise dosimeters are primarily used to measure workers' total noise exposure, especially when the noise levels are varying or intermittent, and the worker moves around frequently during the work shift. Dosimeters are also used to collect data for use in legal proceedings, development of engineering noise controls, and other industrial hygiene purposes.

When planning to conduct noise exposure measurements, steps must be taken to ensure that the dosimeters are calibrated and operated according to manufacturers' specifications. It is also necessary to understand

the properties of the acoustical environment, the main measurement objectives as they relate to determining the risk to hearing, and the limitations associated with the use of dosimeters.

3.1 Dosimeter Calibration

Dosimeter manufacturers recommend that the instrument be calibrated with an acoustical calibrator before and after each measurement to verify reliable operation. In addition to field calibration routines, the manufacturers recommend periodic comprehensive calibration and certification of the instrument by an accredited laboratory using traceable reference sources. Field calibration of contemporary dosimeters has been mostly automated through PC-based programs that run the calibration routine, document the time and date, and adjust for any offset in levels.

Figure 2 shows a Larson-Davis Model 706 dosimeter being calibrated at 114 dB sound pressure level (SPL) (1000 Hz) using the Larson-Davis CAL 150 Precision Acoustic Calibrator.

3.2 Operational Settings

Current dosimeters are designed to provide the user with parameters such as noise dose, time-weighted average, sound exposure level, as well as peak, maximum, and minimum sound pressure levels. Most dosimeters also generate statistical and graphical representations of the collected data. ANSI S1.25 specifies that dosimeters should at least provide the following parameters:

Frequency weighting: A or C
Exponential averaging: F (fast); S (slow)
Criterion level: 90, 85, 84, 80, or V (variable)
Criterion duration: hours
Threshold level: 90, 80, or V (variable)
Exchange rate: 5, 4, or 3

3.3 Personal Exposure versus Area Monitoring

A dosimeter may be used as a personal dose meter or as an environmental area monitor. For personal noise monitoring, the instrument may be placed inside a pocket or clipped to a belt. OSHA requires the microphone of the dosimeter be placed in the "hearing zone" of the side of the worker facing the highest noise levels. The hearing zone is defined as hypothetical sphere of 300 mm radius enclosing the head of the wearer.⁴ ANSI S12.19, Measurement of Occupational Noise Exposure, standard specifies that the microphone be located on the middle-top of the worker's most exposed shoulder and that it be oriented approximately parallel to the plane of the shoulder, as shown in Fig. 3. However, studies have shown that placing the microphone on the person's body can affect measurements by anywhere from an A-weighted sound pressure level of -1 to +5 dB.^{5,6} The amount by which the human body affects measurements depends on the nature of the sound field, the frequency spectrum, the angle of incidence, the absorption of the clothing material, and the position of the microphone on the person. In most industrial settings, the A-weighted sound pressure level

Figure 2 Calibration of a personal noise dosimeter with various components notated and highlighted.

Figure 3 Microphone placement of a noise dosimeter on the shoulder of the wearer.

measurements are typically increased by 0.5 to 1.0 dB when the dosimeter is worn on a person compared with the measurements taken in the undisturbed field.⁷

To alleviate the limitations associated with workers' body distortion, minimize sound survey efforts, and provide better exposure estimates for groups of workers, measurement techniques such as profiling or task-based assessment can be used. The dosimeter's microphone can be mounted on a tripod and placed in the unoccupied worker position. A task-based noise assessment is accomplished by measuring noise varying over time and space for each defined work task.⁸ Task-based measurements depend heavily on the accurate identification of the sound field at all points of the task area and the location of the worker versus time.

4 DOSIMETER LIMITATIONS

In addition to the microphone distortions introduced by the worker head and torso, other environmental and electroacoustical factors can limit dosimeter capability and range of operation.

4.1 Mechanical Vibration

Most microphones and dosimeters are sensitive to mechanical vibration, especially at very high SPLs (above 120 dB). Mechanical vibration may cause the

microphone or electronics to produce spurious signals in the dosimeter measurement and lead to an increase in the time-weighted average (TWA) and noise dose. To minimize the effects of vibration on the instrument, care must be taken to ensure that the microphone, cable, and dosimeter case are secured or isolated from the source of vibration. Dosimeter manufacturers test and report on the effects of mechanical vibrations by vibrating the entire instrument sinusoidally along the three mutually perpendicular axes at acceleration of 0.98 m/s^2 and within the frequency range of 10 and 500 Hz.

4.2 Impulse Noise

ANSI S1.25 specifies that noise dosimeters should be suitable for measurement of impulsive, intermittent, and continuous noise. OSHA regulations and NIOSH recommendations state that no exposure should be permitted above 140 dB peak sound pressure level. Nevertheless, dosimeters have been used for measurements of noise environments that have levels above 140 dB such as in construction, mining, and law enforcement firing ranges. It must be noted, however, that the OSHA regulations and the ANSI S1.25 standard require that dosimeters operate properly up to 140 dB.

NIOSH studies have found that personal noise dosimeters have inherent limitations and are susceptible to producing erroneous results when they are used in predominantly impulsive noise environments such as firing ranges.⁹ These standard dosimeters "clipped" peak noise levels greater than the range of the instrument and acted as if they were at the maximum level of that specified range.

4.3 Measurement Artifacts

Dosimeter microphones are susceptible to inadvertent or intentional tampering by the users. Such tampering may occur by tapping or rubbing the microphone, or by screaming or blowing into the microphone during measurements. Investigations into the potential sound-field contamination of such artifacts showed minimal impact (a fraction of a decibel for thumping and hollering to an A-weighted sound pressure level 1 to 2 dB for blowing with background noises of 85 and 90 dB) on the measured daily TWA when using the OSHA 5-dB exchange rule. However, the use of the International Organization for Standardization (ISO), NIOSH, or ACGIH noise exposure criteria showed much more significant increase (an A-weighted sound pressure level 2 to 5 dB) in the measured TWA.¹⁰ To minimize the effect of such artifacts, most dosimeter microphones are provided with small windscreens that will guard against rubbing and touching, and some isolation against blowing. In addition to the windscreens, contemporary dosimeters are manufactured with built-in keypad locking and programmable automatic timers to reduce the potential for tampering. Finally, close examination of the time-history records can show if any abnormal or unexplained spurious events have occurred during the measurements.

4.4 Wet and Humid Environments

Wet and humid environments present a challenge for collecting personal dosimetry measurements. The dosimeter instrument is typically water resistant and tested to withstand high levels of humidity. However, the microphone's frequency response is usually affected if the relative humidity is high or the temperature of the microphone is close to the dew point. Condensation may occur on the diaphragm of the microphone and can generate intermittent internal noise in the measurement.

When operating a dosimeter in a humid or rainy environment, appropriate all-weather microphones with shields must be selected to prevent water from affecting the diaphragm. Wrapping the microphone or enclosing it using makeshift material should be avoided because it can lead to serious errors in the measurements.

Dosimeter manufacturers test for variations of SPLs over some specified relative humidity range.

4.5 Temperature

Current dosimeters are required to operate properly within ordinary indoor temperature ranges. Permanent damage can occur when they are operated or stored at extreme temperatures. The manufacturers are required to state temperature ranges over which the dosimeter, including the microphone, will meet national and international standards. Typically, dosimeters can be operated safely between -15 and 50°C and can be stored (with the battery removed) at temperatures between -20 and 60°C .

4.6 Electromagnetic Interference

Current dosimeters are required to comply with national and international electromagnetic compatibility standards. Manufacturers test the performance of dosimeters to electromagnetic interference at power-line (50 or 60 Hz) frequencies. However, these standard dosimeters might be susceptible to electromagnetic and radio-frequency interference when operated near sources that generate strong electric and magnetic fields such as arc welders and furnaces, cellular and communications equipment, or induction heaters. ANSI S1.14-1998 (R2003) (Recommendations for Specifying and Testing the Susceptibility of Acoustical Instruments to Radiated Radio-Frequency Electromagnetic Fields, 25 MHz to 1 GHz) provides specification and testing for susceptibility radio-frequency and

electromagnetic fields.¹¹ To check for electromagnetic interference, the microphone might be replaced with a shielded capacitor (or "dummy microphone") with similar impedance. If electromagnetic interference is observed in the dosimeter reading, then action must be taken to shield the instrument.

CHAPTER 40

ANALYZERS AND SIGNAL GENERATORS

Henrik Herlufsen, Svend Gade, and Harry K. Zaveri

Brüel & Kjær

Sound & Vibration Measurement A/s

Naerum, Denmark

1 INTRODUCTION

An analyzer is a device that takes sound or vibration signals and extracts the various forms of information carried in the signals. An understanding of the basic concepts of signal analysis is important for correct use and setup of analyzers when dealing with the various types of noise and vibration signals encountered in practice. It is important to understand what analyzers can offer and provide. Frequency analysis is the most widely used method for solving noise and vibration problems. As the frequency content of the signal is generally related to a specific component of a given system, this method is often the key to a better understanding of the vibrational and acoustical phenomena. The filtering method and use of the fast Fourier transform (FFT) are common approaches for analysis of signals. Systems are often analyzed from measurements of their inputs and outputs. In contrast to a signal analyzer, a signal generator is a device used to generate sound and vibration signals for the purpose of the excitation of systems.

2 ANALYSIS CONCEPTS

2.1 Basic Concepts, Signal Types, and Descriptors

Analysis of noise and vibration signals is performed in order to extract the various forms of information carried in the signals, which have been found to relate to the properties of a structure or a system under investigation. Different analysis techniques are used in order to acquire a specific type of information. The requirement is that the information should be extracted in a form that will make interpretation easier and communication and documentation simpler.

Different analyzers use different analysis techniques and are applied for the various applications. The most fundamental analysis is the determination of the amplitude characteristics and the spectral (frequency) distribution of the signal.

2.1.1 Types of Signals and Spectral Units

The way we treat and analyze signals depends upon the type of signal. Signals can be divided into different categories, with the most basic division being stationary and nonstationary signals. Stationary signals are divided into deterministic and random signals, and nonstationary signals are divided into continuous and transient signals.¹ Examples of the various types in the time and frequency domains are illustrated in Fig. 1.

A unique descriptor for a continuous stationary signal is its root-mean-square (rms) value. It gives

information about the “power” in the signal in the following sense. If the signal is considered as an electrical voltage signal, the rms value is the constant voltage that will dissipate the same power (heat) in a resistor. It is a value in units of the measured quantity (such as pascals for sound measurements or metres per second squared for vibration measurements) and, thus, only a measure of the power in the above-described sense. The square of the rms value, that is, the mean square (MS) value, is related to power in the physical sense via an impedance.

Stationary deterministic signals are made of a combination of sinusoidal signals with different amplitudes and frequencies. The spectrum is characterized by content (power) at discrete frequencies (a line spectrum). This means they have a certain rms value (or MS value) at each of these frequencies and that the sum of the MS values at all the frequencies is the MS value of the signal (neglecting the random noise content, see below). Thus, it is natural to scale the spectra of these signals in terms of rms. In some vibration applications, the spectra are sometimes rescaled to the amplitude of the sine components (the peak value), which is $\sqrt{2}$ rms or in the peak-to-peak value (i.e., twice the amplitude or $2\sqrt{2}$ rms). Noise and vibration signals from rotating machinery with constant speed are examples of this type of signal.

Stationary random signals are described by their statistical properties, such as the mean value, standard deviation, amplitude probability, and so forth. In contrast to stationary deterministic signals, they have a continuous distribution of spectral content.

Random processes give rise to random signals, and all signals encountered in real life have a certain content of this kind of signal. Analysis of random data is a complete discipline in itself and has a wide range of applications. In analysis of deterministic signals, the random content is often referred to as the noise content, and methods are searched for to minimize its influence.

Due to the continuous distribution of spectral content, the natural way to scale the spectra is in terms of *power spectral density (PSD)*, and the power or MS value in a given frequency band is given by the integral of the PSD over the frequency band. The unit of PSD is U^2/Hz , where U is the unit of the measured signal. The square root of the PSD, often called the rms spectral density (rmsSD), has a unit of $U/\sqrt{\text{Hz}}$.

The spectrum of a random signal scaled in rms will thus change in accordance with the measurement bandwidth. This is observed, for example, when a
